is related to copy number of the bound target DNA and deviations from a normalized fluorescence corresponding to two copies of sequence is recorded as gains or losses. Up to 100 distinct microbeads with different fluorescent color codes are available from Luminex, allowing for the detection and quantitation of 100 single copy DNA regions of interest in a single assay. The beauty of this technology is the ability to inexpensively manufacture appropriate microbeads and to analyze hundreds of targets within several hours. Similar analyses have been applied to gene expression studies (Yang *et al*., 2001) and single nucleotide polymorphism identification (Chen *et al*., 2000; Wedemeyer *et al*., 2001), revealing the utility of coupling bead array DNA hybridization with flow cytometry.

7. The end of the beginning

The medical importance of scanning the human genome for abnormalities associated with clinical phenotypes was recognized when the first numerical chromosome aberrations were described (Lejeune *et al*., 1959; Ford *et al*., 1959; Jacobs and Strong, 1959). From their unique study of the genome through the microscope, clinical cytogeneticists have been uncovering the links between patients' abnormal phenotypes and changes in chromosome content or arrangement. Recently, this original form of genome assessment has greatly benefited from technological advances and information being generated from the Human Genome project. Routine chromosome assessment is now coupled with FISH, CGH, and BAC array data to provide high-resolution, sensitive evaluation of human genomes. These techniques have linked traditional cytogenetic banding techniques, capable of identifying aberrations on the megabase scale, with the basic sequence data of molecular biology. Recent developments and future applications will offer unprecedented opportunities to study the relationship between chromosomes and phenotype that will undoubtedly have a significant impact on the practice of medicine.

Specialist Review

Current approaches to molecular diagnosis

O. Thomas Mueller
University of South Florida, St. Petersburg, FL, USA

1. Introduction

Of the approximately 30 000 different genes that have been identified by numerous researchers in the Human Genome Project, relatively few have been associated with specific pathogenic conditions (*see* Article 24, **The Human Genome Project**, Volume 3 and Article 31, **Overlapping genes in the human genome**, Volume 3). It will be a continuing challenge to correlate gene with disease in ways that are clinically useful and meaningful, especially in disorders of complex etiology. Current approaches to the identification of mutations in inherited human disorders encompass a variety of methods, including traditional procedures such as Southern blotting and detection by DNA hybridization as well as novel highly efficient techniques that use real-time polymerase chain reaction (PCR) or gene microarrays. Recognition of the most effective and efficient diagnostic approach for a patient with a suspected diagnosis requires an understanding of the molecular pathology of the suspected syndrome(s), as well as a recognition of the limitation of the diagnostic testing available. In some disorders, the molecular pathology is well defined and an efficient diagnostic protocol is in place; however, for most conditions, the most effective protocols will emerge as research and experience dictate and will require a close interaction of clinical and laboratory professionals. This review will summarize the current approaches to diagnostic techniques in a molecular genetic laboratory, emphasizing the complexities in disorders with trinucleotide repeat expansions and those with genetic imprinting mechanisms.

2. Single base-pair detection methods

2.1. *Allele-specific oligonucleotides (ASO)*

This term describes a variety of techniques that have been used for single nucleotide polymorphism (SNP) detection and are based on the hybridization specificity of short oligonucleotides (*see* Article 71, **SNPs and human history**, Volume 4).

These synthesized DNA sequences of approximately 20 bp are constructed to match specific mutant and wild-type base-pair changes and are used to detect specific known mutations. The detection method of hybridized mutant or wild-type oligonucleotide varies with the different applications (Beckmann, 1988).

2.2. *Allele-specific amplification procedure (ASAP) or allele refractory mutation system (ARMS)*

These techniques are variations of SNP detection techniques that are based on the hybridization specificity of oligonucleotides used as PCR primers. Primers are designed to precisely match a known sequence variation, and a second primer pair that matches the wild-type sequence at the same locus is used in a parallel reaction. The matching/mismatching base is positioned at the 3′ or next to the 3′ end of one of the PCR primers. Successful discrimination of the normal and mutant sequences can usually be achieved by optimizing the PCR conditions. Detection can be as simple as reading the fluorescence of ethidium bromide–stained amplification fragments without electrophoresis or as sophisticated as automated detection of simultaneous fluorescent dye–labeled amplification products.

2.3. *CR detection using fluorescence resonance energy transfer (FRET)*

In the Amplifluor modification of the ARMS (allele refractory mutation system) technique, marketed by Intergen (ITK Diagnostics BV), the mutant and wild-type primers are labeled with different fluorescent dyes, and are used in combination to allow competitive detection. Fluorescence is derived only from amplification products, since the fluorescence of the unincorporated primers is inhibited by a quenching molecule held in proximity by a hairpin structure (Newton, 1989; Wu, 1989; Myakishev, 2001). Amplification correlates directly with fluorescence generated and can be detected either as real time or as an endpoint determination.

Another application of SNP detection is utilized by the Invader reaction, marketed by Third Wave Technologies, Inc. This technology uses two short DNA probes that hybridize with the target at the site of the variation or mutation. The structure that forms from a mismatched hybridization is recognized and released into solution by a Cleavase® enzyme, which cuts DNA at single/double strand junctions. The released DNA fragment is detected by real-time fluorescent resonance energy transfer procedures. In the absence of any sequence variation, the enzyme fails to cleave and no fluorescence is generated.

2.4. *Ligase chain reaction*

This technique detects single-base substitutions at specified base sequences in a targeted DNA sequence. A ligase enzyme links two adjacent oligonucleotides that

hybridize with the target sequence. If a mismatch exists at the site where the two oligonucleotides meet, the ligation of the adjacent oligonucleotides fails, and this sequence will not amplify in subsequent cycles. Oligonucleotides hybridizing with the wild-type sequence will be joined and continue to participate in subsequent cycles. Detection of the SNP mutation, therefore, depends on designing oligos specific for the expected base changes (Barany, 1991).

2.5. Real-time PCR

Real-time PCR is a relatively new procedure, which adapts the sensitivity of fluorescent detection methods to single nucleotide polymorphism (SNP) detection. This method utilizes a system of two different labeled probes that are designed to bind and release a fluorescent emission on the basis of single-base differences. The two probes, designated donor and acceptors, bind adjacent to the site of the mutation or SNP and release fluorescent signals only when there is a perfect hybridization match. Real-time PCR offers several technical advantages over other SNP detection procedures. Since it is based on hybridization of two different probes, there is increased detection sensitivity. In addition, the probe melting temperatures can be determined, allowing mutations to be characterized on the basis of their sequence differences. Finally, the sensitivity of real-time PCR allows more accurate quantitative determination than traditional PCR, allowing applications involving gene expression and viral load measurement.

2.6. Dye-labeled oligonucleotide ligation or template-directed dye-terminator incorporation (TDI) assays

This method is based on SNP detection using the real-time generation of fluorescent signals but incorporates a ligation reaction. Two alternate upstream primers and a universal downstream primer are annealed with the template. The SNP allows the hybridization of only the matching upstream primer, and the ligase connects the upstream and downstream primers to form a new molecule having both fluorescent labels. Specific real-time signal detection is based on fluorescence resonance energy transfer (FRET) (Chen and Kwok, 1997).

The TaqMan assay was developed by (Holland, 1991) and is marketed by Applied Biosystems. This procedure is a Real-time PCR adaptation that uses the 5′-exonuclease activity of the Taq polymerase to detect single nucleotide sequence variations. A DNA probe labeled with donor and fluorescent dyes anneals specifically to the accumulating amplification product, but only when sequence-specific amplification occurs. Exonuclease cleavage of the probe dissociates the donor and quenching acceptor dyes and causes an exponential increase of the fluorescence during amplification, which can be measured spectrophotometrically. Because fluorescence only increases when particular sequences are generated by PCR, this

technique is especially useful in diagnostic applications, such as the detection of pathogens and disease-associated genes (Livak, 1995).

2.7. DNA chips, genome chips, and microarrays

Several novel applications variously termed DNA chips, gene or genome chips, and microarrays are expected to have a major impact on genome research (*see* Article 90, **Microarrays: an overview**, Volume 4 and Article 91, **Creating and hybridizing spotted DNA arrays**, Volume 4). These are different variations of orderly arranged samples of DNA or oligonucleotides that allow automation of gene expression and gene mutation–screening applications. These arrays are assembled using robotics and have DNA or oligonucleotide samples arranged on a nylon or glass backing. Each individual sample is extremely small (less than 200 µm for microarrays and greater than 300 µm for macroarrays), which allows simultaneous screening of a large number of genome loci based on the DNA hybridization principle using imaging technology. Microarrays generally refer to longer (500–5000 bp) DNA sequences that were developed by Stanford University (Ekins and Chu, 1999). Arrays with shorter oligonucleotide probes (20–80 bp) are generally termed DNA-, gene-, or genome chips, with the GeneChip designation a trademark registered by Affymetrix, Inc. Microarrays and gene chips have numerous applications including gene discovery, disease diagnosis, pharmacogenetics, and toxicogenomics (Shi, 1998).

3. Mutation screening methods

Several methods have been described that allow rapid screening of multiple exons or gene regions for mutations. Many of these utilize the characteristics of DNA heteroduplexes, which are formed by the annealing of a wild-type sequence with one that has one or more base-pair changes (presumably pathogenic). In the case of a dominant mutation, where both normal and a mutated sequence are expected, the samples need to be denatured and allowed to reanneal. Both of the native homoduplexes would be expected to reform, but a significant amount of heteroduplex formation containing one or more base mismatches are also formed and are the basis of these methods. In recessive disorders, where both copies of a gene or segment may be identical, these detection methods require that specimens to be analyzed are mixed with control DNA samples.

3.1. Denaturing gradient gel electrophoresis (DGGE)

This method can be used to rapidly screen for mutations in PCR-amplified exons suspected to have a mutation. This method uses the different denaturation properties of mismatched heteroduplex and homoduplex DNA fragments in carefully defined temperature and denaturant conditions. These melting differences cause them to migrate differently in polyacrylamide gels. Although this method is useful to screen

a large number of exons for suspected mutations, the detection rate is estimated to be approximately 70–95%, since not all base-pair changes are identified. The specific base-pair change must be identified by DNA sequencing and discriminated from nonpathogenic DNA polymorphisms (Myers *et al*., 1985).

3.2. Denaturing detergent gradient gel electrophoresis (DDGE)

DDGE is based on the different melting properties of heteroduplex and homoduplex DNA sequences, but uses detergent gradients to denature them. Single- versus double-stranded segments have different electrophoretic migration easily detected on acrylamide gels (Sheffield, 1989).

3.3. Single-stranded conformational polymorphism (SSCP)

SSCP is a mutation screening procedure that is based on secondary and tertiary structure differences that occur between single-strand DNA segments that have one or more base-pair changes. DNA segments are denatured, rapidly cooled, and resolved on nondenaturing polyacrylamide gels. Differently migrating SSCP alleles suggest a base-pair change that must be identified by DNA sequence analysis (Orita, 1989; Antolin, 1996).

3.4. Denaturing high-pressure liquid chromatography (DHPLC)

This method is proving to be a valuable tool used for identifying DNA sequence variations based on slight differences in their duplex melting temperatures. High-pressure liquid chromatography has had numerous applications in medicine, but when ion-paired reversed-phase columns were developed by Peter Oefner and Christian Huber, their application expanded to the detection of DNA variations. Mutations in over 350 different disease-associated genes have been analyzed using this method. At present, the DHPLC technology is available in two different formats. In the WAVE system marketed by Transgenomic, Inc., the columns are packed with alkylkated poly(styrene-divinylbenzene) particles (Bonn, 1996). Varian offers the Helix DHPLC system that uses columns containing 1000-Å alkylated silica. Methods can be developed for screening unknown mutations or detecting known SNP sites. The sensitivity of mutation detection protocols has been reported over 90%, and can depend on the estimated melting temperature parameters (Ravnik-Glavac, 2002).

3.5. Cleavase fragment length polymorphism (CFLP)

This method is a mutation screening method based on sequence-dependant secondary structure variations, as in SSCP. DNA fragments are amplified, denatured by heating, and cooled to a predetermined temperature. However, unlike SSCP, these sequences are resolved by using an endonuclease, Cleavase I, to make specific cuts between single- and double-stranded regions. Following electrophoresis, any

changes in the specific bonding pattern suggests a base change that must be identified by DNA sequence analysis (Brow, 1996).

4. DNA sequencing methods

In a diagnostic laboratory, the mutation screening methods described above are useful tools to help identify small DNA alterations; however, the gold standard remains in identifying specific alterations by DNA sequence analysis (*see* Article 4, **Sequencing templates – shotgun clone isolation versus amplification approaches**, Volume 3). A number of different DNA sequencing methods based on the di-deoxy termination chemistry of Sanger (1977) are used, as well as several that use alternate methods.

4.1. Polyacrylamide-based sequencing systems

Several DNA sequencing systems utilize polyacrylamide gel electrophoresis to separate DNA fragments. LI-COR, Inc, offers a DNA sequencing system that uses an infrared detection system to detect two different dye-labeled dideoxy nucleotides, which allows relatively long reads and simultaneous bidirectional sequencing. Visible Genetics, Inc. has developed multiple systems, including MicroGene Blaster™, the MicroGene Clipper™, the Long-Read Tower™, and the OpenGene DNA Sequencing System, which uses disposable MicroCel cassettes with different read lengths. Their TRUGENE HIV-1 genotyping kit including the OpenGene DNA Sequencing System was the first DNA sequencing–based test to receive FDA approval.

4.2. Sequencing sytems based on capillary electrophoresis

Several other manufacturers offer systems that incorporate capillaries containing renewable polymers to separate the DNA sequencing fragments. Amersham Biosciences markets several DNA sequence analysis platforms that are intended for either medium-throughput usage (ALFexpress™, a single dye system that uses polyacrylamide gels) or high-throughput usage (MegaBACE™, which provides for simultaneous use of up to 348 capillaries). Beckman Coulter offers the CEQ 8800 Genetic Analysis System, which is a capillary-based system that features linear polyacrylamide gels, coated capillaries, and cyanine-based infrared dyes that also allows fragment analysis, SNP detection, and amplified fragment length polymorphism (AFLP) fingerprinting. Applied Biosystems has several DNA sequencers that utilize 4 or 5 color dye–based sequencing with capillary electrophoresis. They vary in capability from the single capillary ABI Prism 310 Genetic Analyzer, the 4- or 16-capillary ABI Prism 3100-Avant and 3100

Genetic Analyzers, to the Applied Biosystems 3730 DNA Analyzer, with up to 96 capillaries.

4.3. *Novel methodologies*

Other corporations have developed novel alternatives to the Sanger di-deoxy terminator–based chemistry. The Pyrosequencing™ technology, marked by Biotage AB, is based on a series of enzymatic reactions, whereby the nucleotides are detected as they are sequentially added to a DNA template. A sulfurylase reaction detects the release of pyrophosphate, converting luciferin to oxyluciferin, and a luciferase catalyzes the release of light signals with each addition of nucleotides. The DNA sequence is determined by the pattern and intensity of light signals generated as nucleotides are added to the template. One report claims 96 sequence analyses within 20–30 min (Alderborn, 2000). Several other alternate DNA sequencing methods have been in development; however, they have not come into common usage in a DNA diagnositic laboratory. These include matrix-assisted laser desorption/ionization DNA sequencing (Fitzgerald, 1993) and DNA sequencing by oligonucleotide hybridization (Dramanac, 1993).

5. Current approaches for specific disorders

5.1. *Disorders caused by trinucleotide repeat expansion*

Over a dozen disorders have been identified that are caused by expansions of trinucleotide repeat tracts. The trinucleotide repeat varies with the specific disorder, although $(CAG)_n$ is most common, and occurs most often in the 5′-UTR or the first exon of the expanded gene. Interestingly, many of these disorders are late-onset neuropathies that are progressive and are inherited as autosomal dominant conditions. Since the mutation in these disorders is strictly a size abnormality, laboratory detection of these disorders is accomplished by PCR amplification of the specific gene region containing the repeat followed by accurate measurement of the fragment size generated. Polyacrylamide gel or capillary electrophoresis is commonly used in order to maximize sizing accuracy, with Southern blotting used only to confirm the presence of exceptionally large gene expansions, and DNA sequencing is used to identify mutations in nonexpansion cases. In several disorders, fragile X syndrome, myotonic dystrophy, and spinocerebellar ataxia type X, the extent of the gene expansion is substantially more than the others (hundreds of trinucleotide repeats in affected individuals), and a Southern blot strategy is usually employed in order to detect and size the expanded alleles. The former disorders are associated with a total loss of gene function associated with failure of gene transcription, whereas those disorders with more subtle gene expansions are associated with a gain of abnormal deleterious function. For instance, those disorders with CAG expansions are transcribed into polyglutamine runs, which migrate to the nucleus of affected cells and form insoluable protein deposits that cause damage to the peripheral neurons.

5.1.1. Intermediate size alleles

The length of the trinucleotide repeat is extremely polymorphic in normal individuals as well as in affected persons. This size variability is most likely associated with replication errors of these repetitive tracts during evolution. For many of these conditions, there is a significant gap between the normal size alleles range and those that are pathogenic, which is termed the intermediate size range or premutation range. The accurate detection of the exact repeat length is often of importance since there are different risks associated with different sizes of intermediate alleles in most of these conditions. Intermediate size gene expansions are known to be unstable, and the risk of expansion into pathogenic alleles varies with the size of the premutation. In addition, there may be mild symptoms associated with intermediate size genes, as in Huntington disease. The American College of Medical Genetics has issued a policy statement with specific recommendations for Fragile X Syndrome: Fragile X Syndrome: Diagnostic and Carrier Testing (July 22, 1994) and Technical Standards and Guidelines for Fragile X (Maddalena, 2001). They recommend diagnostic testing to include accurate determination of the size of the smaller normal and premutation alleles (e.g., polyacrylamide electrophoresis), as well as a second method (Southern blotting) targeted for detection of the large expansions.

5.1.2. Genetic anticipation

Many of the trinucleotide expansion disorders demonstrate extremely variable clinical expressivity. This is termed genetic anticipation when symptoms appear to become dramatically more severe within a single generation of a family. Genetic anticipation is more often associated with maternal transmission of the affected gene in some disorders (Fragile X syndrome, myotonic dystrophy) and with paternal transmission of the affected gene expansion in others (Huntington disease, most forms of spinocerebellar ataxia). These changes are often associated with dramatic changes in the length of the trinucleotide repeat, and laboratory testing of extended family members are often useful for accurate risk prediction and genetic counseling. An example is myotonic dystrophy, whose severity varies dramatically with the extent of expansion. Adults can have mild symptoms and are undiagnosed until a dramatic gene expansion occurs in their congenitally affected child. DNA testing measures the length of the repeated CTG pattern in the 3′-untranslated region of the *DMPK* gene. Normal individuals have from 5 to 30 repeat copies; mildly affected persons have from 50 to 80; and congenital onset forms have been described with 2000 or more copies. A combination of methods that allow both accurate sizing of the normal and smaller affected alleles (PCR and polyacrylamide gels) as well as sensitive detection of large expansions (Southern blotting with probe hybridization detection) is the recommended protocol.

5.2. Prader–Willi and Angelman syndromes: cytogenetics versus molecular analysis

Prader–Willi syndrome (PWS) is characterized by severe hypotonia and feeding difficulties in early infancy, followed by uncontrolled appetite (hyperphagia) and

severe obesity in childhood. All patients have mild to moderate mental retardation and, often, behavioral problems. Patients have hypogonadism and infertility. Angelman syndrome (AS) presents in early childhood with hypotonia followed by motor and intellectual retardation. Affected children are ataxic, epileptic, have absence of speech, and an unusual facies characterized by a large mandible and an open-mouthed expression. Patients demonstrate excessive laughter, an occipital groove, abnormal choroidal pigmentation, and characteristic electroencephalogram (EEG) discharges. PWS and AS are caused by a variety of etiologies, including specific 4-megabase deletions of chromosome 15q11-q12, uniparental disomy of chromosome 15, chromosomal translocations, imprinting center mutations, or specific gene mutations (Table 1). Their different clinical presentations are explained by the absence of specific imprinted genes in this chromosomal region that are either paternal in origin (PWS) or maternal (AS).

The presence of imprinted genes, which are either active or inactive depending on their parent of origin, is unusual on an autosome, although examples of other genes on chromosomes 7, 11, 14, and others exist (*see* Article 49, **Gene mapping, imprinting, and epigenetics**, Volume 1). However, when the normal biallelic inheritance of these genes is disrupted by chromosomal deletions or the inheritance of both chromosomal copies from only one parent (uniparental disomy), then the lack of one set of imprinted genes causes a clinical phenotype: PWS, when the absent genes are paternal in origin, or AS when they originated from the mother. DNA methylation analysis of the *SNRPN* gene in the PWS/AS critical region is performed as the preliminary screen in addition to a routine karyotype. If the methylation test is positive, the diagnosis is confirmed by testing for a deletion by fluorescent in situ hybridization (FISH) and for uniparental disomy (UPD) by microsatellite analysis. Specimens from the parents of the proband are required to establish either isodisomy (same chromosome from one parent that is present in duplicate) or heterodisomy (different chromosomes inherited from the same parent).

The American Society of Human Genetics and the American College of Medical Genetics has issued a position statement recommending the testing protocol for suspected PWS or AS patients (American Society of Human Genetics/American College of Medical Genetics Test and Transfer Committee, 1996). There are two strategies that differ somewhat depending on the specific circumstances of the patient. If the symptoms are not clearly suggestive of PWS or AS, then they recommend cytogenetic testing to identify the chromosome 15 deletion or another cytogenetic abnormality. If these results are normal, then molecular genetic testing to detect methylation or uniparental disomy is indicated. However, if the patient fits the diagnosis of PWS or AS more closely, then molecular methods could be used as the initial screen. If the methylation results are positive, then FISH analysis (for a deletion), microsatellite analysis (for unipatental disomy), or imprinting mutations are done subsequently. The type of abnormality is crucial for accurate risk assessment and genetic counseling. Although both deletion-type PWS and AS and those caused by uniparental disomy are de novo and there is a low recurrence risk, imprinting center mutations have a high recurrence risk.

Table 1 Current approaches to molecular genetic diagnosis of selected syndromes

Disorder or syndrome	Gene, map location	Protein product	Mutation type(s): % detected	Diagnostic methods	Inheritance or mutation comments
Achondrogenesis type 1B	SLC26A2 5q32-q33.1	Sulfate transporter	Common mutations detect 60%: R279W, IVS1+2T>C, delV340, R178X; Other base changes: 30%	Sequence analysis	Autosomal recessive inheritance
Albright hereditary osteodystrophy, pseudohypopara-thyroidism, IA	GNAS 20q13.2	Guanine nucleotide binding protein G(S), alpha subunit	Point mutations, deletions, and insertions	Sequence analysis	Inheritance is autosomal dominant but sex-influenced
Alport syndrome	COL4A5 Xq22.3	Collagen alpha 5(IV) chain	Base-pair substitutions in glycine codons: > 60%	Sequence analysis	80% of Alport sydrome are X-linked
	COL4A3 2q36-q37	Collagen alpha 3(IV) chain	Assorted base-pair mutations	Sequence analysis	15% of Alport sydrome are autosomal recessive
	COL4A4 2q36-q37	Collagen alpha 4(IV) chain	Unknown	Sequence analysis	5% of Alport sydrome are autosomal dominant
Alzheimer disease, early onset familial	PSEN1, 14q24.3	Presenilin 1	PSEN1 mutations account for 30–70%	Sequence analysis	Assorted base-pair changes: 6% with no family history
	APP, 21q21	Amyloid beta A4 protein	APP mutations account for 10–15%	Sequence analysis	Assorted base-pair changes
	PSEN2, 1q31-q42	Presenilin 2	PSEN2 mutations account for <5%	Sequence analysis	Assorted base-pair changes
Androgen insensitivity syndrome	AR xq11-q12	Androgen receptor	Point mutations, deletions, and insertions	Sequence analysis	Complete AIS: 95% Partial AIS: ~50% Mild AIS: unknown
Angelman syndrome	UBE3A 15q11.2-q13	Ubiquitin-protein ligase E3A	Methylation abnormality: 78%	Southern blot methylation-sensitive PCR	Deletions and UPD are usually de novo mutations, with a low recurrence risk. UBE3A and imprinting center defects are inherited as sex-limited autosomal dominant
			Deletion of 3–5 Mb: 68%	FISH	

			Uniparental disomy of chromosome 15: ~7%	Microsatellite analysis	
			UBE3A point mutations: ~11%	Sequence analysis	
			Imprinting defects: 3%	Sequence analysis	
Aniridia, isolated	PAX6, 11p13	Paired boxprotein Pax-6	Mutations found in 90% of familial aniridia cases	Sequence analysis	Autosomal dominant inheritance
Atelosteogenesis type 2	SLC26A2 5q32-q33.1	Sulfate transporter	Common mutations detect 60%: R279W, IVS1+2T>C, delV340, R178X, Other base changes: 30%	Sequence analysis	Autosomal recessive inheritance
Bardet–Biedl syndrome (BBS)	BBS1, 11q13 BBS2, 16q21 BBS4, 15q22 MKKS, 20p12 BBS7, 4q27	Bardet–Biedl syndrome proteins 1, 2, 4, 7, McKusick–Kaufman Sydrome	Assorted base-pair changes: common mutation in BBS1M390R is present in 18–46%	Mutation scanning, sequencing	Autosomal recessive inheritance
Becker muscular dystrophy	DMD Xp21.1	Dystrophin	Intergenic deletions (rare) intragenic deletions: 85%	Southern blot, Multiplex PCR, FISH	Most deletions preserve the reading frame; mutations are missense substitutions
			Intragenic duplications: 6%	Southern blot, Multiplex PCR, FISH	
			Point mutations: 10%	Sequence analysis	
Beckwith–Wiedemann syndrome	KCNQ1OT1, 11p15	Potassium channel antisense transcript	Methylation abnormalities in KCNQ1OT1: 50%; H19: 2–7%	Methylation analysis	Uniparental disomy of chromosome 11 in 10–20% of cases
	CDKN1C 11p15	Cyclin-dependent kinase inhibitor	Mutations in CDKN1C in 5–10% of simplex and 40% of familial cases	Sequence analysis	
Berardinelli–Seip congenital lipodystrophy	AGPAT2 9q34.3	1-acyl-sn-glycerol-3-phosphate acyltransferase beta	Assorted base-pair changes: 39% in AGPAT2	Mutation scanning, sequence analysis	Autosomal recessive inheritance
	BSCL2 11q13	Seipin	Assorted base-pair changes: 55% in BSCL2		

(*continued overleaf*)

Table 1 (*continued*)

Disorder or syndrome	Gene, map location	Protein product	Mutation type(s): % detected	Diagnostic methods	Inheritance or mutation comments
Biotinidase deficiency	BTD 3p25	Biotinidase	Assorted base-pair changes: G98:d7i3, Q456H, R538C, D444H, and D444H/A171T	Sequence analysis	Partial biotinidase deficiencies are compound heterozygous with D444H
Branchiootorenal syndrome	EYA1 8q13.3	Eyes absent homolog 1	Assorted base-pair changes detected in 40% of cases	Sequence analysis	Autosomal dominant inheritance
Breast cancer	BRCA1 17q21	Breast cancer type 1 susceptibility protein	Assorted base-pair changes detected in *BRCA1* or *BRCA2* genes in 63% of cases	Mutation scanning, sequence analysis	Autosomal dominant inheritance
	BRCA2 13q12.3	Breast cancer type 2 susceptibility protein			
Childhood ataxia with central nervous system hypomyelination	EIF2B1 12	Translation initiation factor eIF-2B alpha subunit	Assorted base-pair changes: detected in 1% of cases	Sequence analysis	
	EIF2B2 14q24	Beta subunit	Assorted base-pair changes: detected in 14% of cases		
	EIF2B3	Gamma subunit	Assorted base-pair changes: detected in 5% of cases		
	EIF2B4, 2p23.3	Delta subunit	Assorted base-pair changes: detected in 10% of cases		
	EIF2B5 3q27	Epsilon subunit	Assorted base-pair changes: detected in 70% of cases		
Charcot-Marie-Tooth disease, CMT1A	PMP22 17p11.2	Peripheral myelin protein 22	PMP22 gene duplication: 76%	FISH	Autosomal dominant inheritance
			PMP22 gene point mutations: unknown	Sequence Analysis	
Charcot-Marie-Tooth disease, CMT1B	MPZ 1q22	Myelin P0 protein	*MPZ* gene point mutations: 5–10%	Sequence Analysis	Autosomal dominant inheritance
Charcot-Marie-Tooth disease, CMT1D	EGR2 10q21.1-q22.1	Early growth response protein 2	*EGR2* gene point mutations: unknown	Sequence analysis	Autosomal dominant inheritance
Charcot-Marie-Tooth disease, CMT2E	NEFL 8p21	Neurofilament triplet l protein	*NEFL* gene point mutations: unknown	Sequence analysis	Autosomal dominant inheritance

Charcot-Marie-Tooth disease, CMT4A	GDAP1 8q13-q21.1	Ganglioside-induced differentiation protein 1	*GDAP1* gene point mutations: unknown	Sequence analysis	Autosomal recessive inheritance
Charcot-Marie-Tooth disease, CMT4E	EGR2 10q21.1-q22.1	Early growth response protein 2	*EGR2* gene point mutations: unknown	Sequence analysis	Autosomal recessive inheritance
Charcot-Marie-Tooth disease, CMT4F	PRX 19q13.1-q13.2	Periaxin	*PRX* gene point mutations: unknown	Sequence analysis	Autosomal recessive inheritance
Charcot-Marie-Tooth disease, CMTX	GJB1 Xq13.1	Gap junction beta-1 protein (connexin 32)	*GJB1* gene point mutations: 90% of CMTX	Sequence analysis	X-linked dominant inheritance
Choroideremia	CHM Xq21.2	Rab proteins geranyl-geranyltransferase component A 1	Assorted base-pair changes: 60–95%; Common mutation: exon C, insT in the Finnish population	Sequence analysis	X-linked recessive inheritance
Cockayne syndrome, Xeroderma Pigmentosum	CKN1 Chr 5	Cockayne syndrome WD-repeat protein CSA	25% of patients have CKN1 mutations or deletions	Sequence analysis, deletion detection	Autosomal recessive Inheritance
	ERCC6 10q11	Excision repair protein ERCC-6	75% of patients have ERCC6 mutations or deletions		
Coffin–Lowry syndrome	RPS6KA3 Xp22.2-p22.1	Ribosomal protein S6 kinase alpha 3	Base-pair changes: 60–70% by protein truncation; 35–40% by sequence analysis	Mutation scanning; protein truncation	X-linked dominant Inheritance
Congenital adrenal hyperplasia	CYP21A2 6p21	Cytochrome P450 XXIB	Base-pair changes: Nine common substitutions and deletions: 90–95%	Sequence analysis	Autosomal recessive Inheritance
Congenital muscular dystrophy	LAMA2 6q22-q23	Laminin alpha 2	Point mutations: 50%	Sequence analysis	Autosomal recessive Inheritance
Congenital muscular dystrophy	ITGA7 12q13	Integrin alpha-7	Point mutations: ∼3%	Sequence analysis	Autosomal recessive Inheritance
Congenital muscular dystrophy	FKRP 19q13.3	Fukutin-related protein	A retrotransposal insertion in the 3′UTR: 87%	Southern blot	Autosomal recessive Inheritance

(*continued overleaf*)

Table 1 (*continued*)

Disorder or syndrome	Gene, map location	Protein product	Mutation type(s): % detected	Diagnostic methods	Inheritance or mutation comments
Congenital myasthenic syndrome	CHRNA1 2q24-q32	Acetylcholine receptor protein, alpha chain	Assorted mutations found in 50–70% of patients. One common mutation found in 50% of European patients: 1267delG	Sequence analysis	Autosomal recessive inheritance; occasionally autosomal dominant
	CHRNB1 17p12-p11	Acetylcholine receptor protein, beta chain			
	CHRND 2q33-q34	Acetylcholine receptor protein, delta chain			
	CHRNE 17p13-p12	Acetylcholine receptor protein, epsilon chain			
	RAPSN 11p11.2-p11.1	43 kDa receptor-associated protein of the synapse	Assorted mutations found in 20–25% of patients		
	COLQ 3p24.2	Acetylcholinesterase collagenic tail peptide	Assorted mutations found in 15% of patients		
	CHAT 10q11.2	Choline *O*-acetyltransferase	Assorted mutations found in 5% of patients		
Cystic fibrosis	CFTR 7q31.2	Cystic fibrosis transmembrane conductance regulator	900 assorted base-pair changes are known. Common mutation: Delta F508: 66% (in Caucasians)	Assorted multiplex PCR techniques	Most common autosomal recessive disorder in Caucasians
Cystinosis	CTNS 17p13	Cystinosin	Assorted base-pair changes; common mutations: 57 kb deletion exon 1-10; W138X	Mutation scanning, sequencing	Autosomal recessive
Deafness-dystonia-optic neuronopathy syndrome	TIMM8A Xq22	Mitochondrial import inner membrane translocase subunit TIM8 A	TIMM8A deletions, missense, and nonsense mutations at unknown rates.	Sequence and deletion analysis	X-linked recessive inheritance

Dentatorubral – pallidoluysian atrophy	DRPLA 12p13.31	Atrophin-1 related protein	Trinucleotide (CAG) repeat expansion	PCR, PAGE	CAG expansion ranges: Normal: < 35 Affected: 48–93
DiGeorge syndrome	DiGeorge critical region, [UFD1L] 22q11.3	Contiguous genes, [Ubiquitin fusion degradation 1–like]	Deletions found in >95%; Mutations in UFD1L found in <5%	FISH, Sequence analysis	93% of deletions are denovo; 7% are inherited as autosomal dominant
Duchenne muscular dystrophy	DMD Xp21.1	Dystrophin	Intergenic deletions (rare); intragenic deletions: 65%	Southern blot Multiplex PCR, FISH	Intergenic deletions may have retinitis pigmentosa, chronic granulomatous disease, and McLeod red cell phenotype or glycerol kinase deficiency and adrenal hypoplasia
			Intragenic duplications: 6%	Southern blot Multiplex PCR, FISH	
			Point mutations: 30%	Sequence analysis	
Dystonia	DYT1 9q34	Torsin A	Codon 310 GAG deletion: 100%	Sequence analysis	Autosomal dominant inheritance
Episodic ataxia, (EA1)	KCNA1,12p13	Voltage-gated potassium channel protein Kv1.1			Autosomal dominant inheritance
Episodic ataxia, (EA2)	CACNA1A 19p13	Voltage-dependent P/Q-type calcium channel alpha-1A subunit			
Episodic ataxia, (EA2)	CACNB4 2q22-q23	Dihydropyridine sensitive L-type, calcium channel beta-4 subunit			Autosomal dominant inheritance
Facioscapulohumeral muscular dystrophy (FSHD)	Unidentified 4q35	Unknown	D4Z4 repeat region deletion: 95–100%	PFGE with restriction digestion	Repeat size ranges: Normal: 42 kb Grey zone: 35–41 kb Affected: <35 kb
Factor V Leiden thrombophilia	F5 1q23	Coagulation factor V	G1691A (R806G): 100%	PCR, restriction digestion	Population freq: 3–8%

(*continued overleaf*)

Table 1 (*continued*)

Disorder or syndrome	Gene, map location	Protein product	Mutation type(s): % detected	Diagnostic methods	Inheritance or mutation comments
					Patients with deep vein thrombosis: 15–20%
Familial adenomatous polyposis coli, Gardner syndrome	APC 5q21-q22	Adenomatous polyposis coli protein	Over 800 base-pair changes: Most cause premature protein termination	Protein truncation, sequence analysis	Autosomal dominant inheritance
Fragile X syndrome	FMR1 Xq27.3	Fragile X mental retardation 1 protein (FMRP)	Trinucleotide (CGG) repeat expansion	PCR, PAGE, Southern blot for large expansions	Expansion ranges: Normal: 4–44 Intermediate: 45–58 Premutation: 59–330 Affected: over 200 to several thousand
Friedreichs ataxia	FRDA 9q13	Frataxin	Trinucleotide (GAA) repeat expansion	Long-range PCR, Southern blot	Expansion ranges: Normal: 5–33 Premutation: 34–60 Affected: 66–1700
Fukuyama congenital muscular dystrophy	FCMG 9q31	Fukutin	A 3-kb insertion in the 3′ noncoding region: 87%	Sequence analysis	
Hemochromatosis	HFE 6p21.3	Hereditary hemochromatosis protein	Specific base-pair substitutions: C282Y and H63D	PCR and restriction digestion	C282Y homozygotes: 85%; C282Y/H63D compound heterozygotes: <10% Others: <12%
Hereditary hearing loss, nonsyndromic, autosomal dominant (DNFA)	GJB2 13q11-q12	Gap junction beta-2 protein (connexin 26)	Assorted base-pair changes: 100%; common mutations are W44C and C202F		DNFA mutation are heterozygous
	GJB6 13q12	Gap junction beta-6 protein (connexin 30)	Assorted base-pair changes: unknown		
	COCH 14q12-q13	Cochlin			
Hereditary hearing loss, nonsyndromic, autosomal recessive (DNFB)	GJB2 13q11-q12	Gap junction beta-2 protein (connexin 26)	Common mutations: 35delG; 167delT; 235delC Large 342-kb deletions including part of GJB6: 2%	Sequence analysis; deletion analysis	DFNB mutations are homozygous or compound heterozygous

	GJB6 13q12	Gap junction beta-6 protein (connexin 30)	Large 342-kb deletions including part of GJB2: 2%		
	SLC26A4 7q31	Pendrin			
Hereditary hearing loss, nonsyndromic, mitochondrial	MTRNR1	Mitochondrial 12S rRNA			Mitochondrial (maternal) inheritance
	MTTS1	Mitochondrial tRNA serine 1			
Hereditary hearing loss, nonsyndromic, X-linked	POU3F4 [BRN4] Xq21.1	Pou domain, class 3, transcription factor 4			X-linked inheritance
Hereditary multiple exostoses	EXT1, 8q24	Exostosin-1	Assorted base changes detected in >70%	Sequence analysis	Autosomal dominant inheritance
	EXT2 11p12-p11	Exostosis-2			
Hereditary neuropathy with liability to pressure palsies (HNPP)	PMP22 17p11.2	Peripheral myelin protein 22	*PMP22* gene deletions	FISH	Autosomal dominant inheritance
Holoprosencephaly, nonsyndromic	SHH 7q36	Sonic hedgehog protein	Mutations detected: 30–40%	Sequence analysis	Autosomal dominant inheritance
	ZIC2 13q32	Zinc-finger protein ZIC2	Mutations detected: 5%		
	SIX 2p21	Homeobox protein SIX3	Mutations detected: 1.3%		
	TGIF 18p11.3	5′-TG-3′ interacting factor	Mutations detected: 1.3%		
Huntington disease	IT-15 4p13	Huntington	Trinucleotide (CAG) repeat expansion in >99%	PCR, PAGE	Expansion ranges: Normal: 9–25 Mutable: 26–34 Intermediate: 35–38 Affected: 39–120
Jervell and Lange–Nielsen syndrome	KCNQ1 11p15.5	I_{Ks} K+ channel alpha subunit	Assorted base-pair substitutions: >90%	Mutation scanning, sequence analysis	Autosomal recessive inheritance

(*continued overleaf*)

Table 1 (*continued*)

Disorder or syndrome	Gene, map location	Protein product	Mutation type(s): % detected	Diagnostic methods	Inheritance or mutation comments
	KCNE1 21q22.1-q22.2	I_{Ks} K+ channel beta subunit	Assorted base-pair substitutions: <10%		
Juvenile polyposis syndrome	MADH4 (SMAD4) 18q21.1	Mothers against decapentaplegic homolog 4	Assorted MADH4 mutations: 20%	Sequence analysis	Autosomal dominant inheritance
	BMPR1A 10q22.3	Bone morphogenetic protein receptor type IA	Assorted BMPR1A mutations: 23%		
Leber hereditary optic neuropathy (LHON)	mtDNA genes: MTND1, MTND4, MTND5, MTND6	mtDNA NADH-ubiquinone oxidoreductase chain 1, 4, 5, 6	Specific mtDNA base-pair substitutions: G11778A, T14484C, G3460A: 95% of cases	Sequence analysis	Mitochondrial (maternal) inheritance; genotype/phenotype correlations: G11778A is most severe, G3460A is intermediate, and T14484C is mildest.
Leigh syndrome, mtDNA-associated	MTATP6 gene of mtDNA	ATP synthase A6	Base-pair substitutions: MTATP6: T8993G or T8993C: 10–20%	Sequence analysis	Mitochondrial (maternal) inheritance; other genes involved: MTTL1, MTTK, MTND1, MTND3, MTND4, MTND5, MTND6, MTCO3, MTTW, MTTV
Li–Fraumeni syndrome	TP53 17p13.1	Cellular tumor antigen P53	Assorted alterations in P53 gene detected in ~95%; most are missense mutations in exons 5–8.	Sequence analysis, DNA chip detection	Autosomal dominant inheritance
	CHEK2 22q12.1	Serine/threonine-protein kinase Chk2			
Limb–Girdle muscular dystrophy, autosomal dominant	TTID 5q31	Myotilin	Assorted base-pair changes	Sequence analysis	Autosomal dominant inheritance
	LMNA 1q21.2	Lamin A/C			
	CAV3 3p25	Caveolin-3			

	COL6A1, 21q22.3	Collagen alpha 1(VI) chain			
	COL6A2 21q22.3	Collagen alpha 2(VI) chain			
	COL6A3 2q37	Collagen alpha 3(VI) chain			
Limb–Girdle muscular dystrophy, autosomal recessive	SGCA 17q12-q21.3	Alpha-sarcoglycan	Assorted base-pair changes	Sequence analysis	Autosomal recessive inheritance
	SGCB 4q12	Beta-sarcoglycan			
	SGCG 13q12	Gamma-sarcoglycan			
	SGCD 5q33	Delta-sarcoglycan			
	CAPN3 15q15	Calpain 3			
	DYSF 2p13	Dysterlin			
	TCAP 17q12	Telethonin			
	TRIM32 9q31-q34.1	Zinc-finger protein HT2A	D487N homozygous mutation: 100%		
	FKRP 19q13	Fukutin-related protein			
Long QT syndrome, Romano–Ward syndrome	KCNQ1 11p15.5	I_{Ks} K+ channel alpha subunit	LQT1, Assorted base-pair substitutions: 55–60%	Sequence analysis	Autosomal dominant: other genes involved: LQT4 (unknown), LQT5 (KCNE1), LQT6 (MiRP1/KCNE2), LQT7 (unknown)
	HERG 7q35-q36	I_{Ks} K+ channel alpha subunit	LQT2, Assorted base-pair substitutions: 35–40%		
	SCN5A 3p21-p24	I_{Na} Na+ channel alpha subunit	LQT3, Assorted base-pair substitutions: 3–5%		
Machado–Joseph disease	MJD 14q24.3-q31	Machado–Joseph disease protein	Trinucleotide (CAG) repeat expansion	PCR, PAGE	Autosomal dominant; expansion ranges: Normal: up to 47 Intermediate: 48–51 Affected: 53–86
Malignant hyperthermia susceptibility	RYR1 19q13.1	Ryanodine receptor type 1	Base-pair changes: 70% Mutation panel detects 25–30%	Sequence analysis	

(*continued overleaf*)

Table 1 (*continued*)

Disorder or syndrome	Gene, map location	Protein product	Mutation type(s): % detected	Diagnostic methods	Inheritance or mutation comments
Marfan syndrome	FBN1 15q21.1	Fibrillin 1	Point mutations: 30–90% Detection rate depends on strength of diagnostic criteria met	Mutation screening, sequence analysis	Autosomal dominant inheritance
Medium-chain acyl-coenzyme A dehydrogenase deficiency	ACADM 1p31	Medium-chain acyl-CoA dehydrogenase (MCAD)	One common mutation, K304E present in 76%; Assorted base-pair changes: 95%	Sequence analysis	Autosomal recessive inheritance
Megalencephalic leukoencephalopathy with subcortical cysts	MLC1 22qter	Membrane protein MLC1	Assorted base-pair changes detected in 60–70%	Sequence analysis	Autosomal recessive inheritance
MELAS (Mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes)	MTTL1 gene of mtDNA	tRNA $^{Leu(UUR)}$	Base-pair substitutions: MTTL1 A3243G: 80% MTTL1T3271C: ~7.5% MTTL1 A3252G: ~7.5 – 10%	Sequence analysis	Mitochondrial (maternal) inheritance
McCune–Albright syndrome	GNAS 20q13.2	Guanine nucleotide-binding protein G(S), alpha subunit	Point mutations, deletions, and insertions	Sequence analysis	Few familial cases; GNAS mutations are mosaic
Familial medullary carcinoma of the thyroid (FMTC)	RET 10q11.2	RET oncogene	Point mutations in 88% of FMTC; especially, cysteine codons in exons 10, 11, 13–15:	Sequence analysis	Autosomal dominant inheritance
Menkes disease	ATP7A Xq13-q13	Copper-transporting ATPase 1	Point mutations and deletions: 95%	Mutation scanning: Sequence analysis	X-linked recessive inheritance
Methylenetetrahydro-folate reductase thrombophilia	MTHFR 1p36.3	Methylenetetrahydro-folate Reductase	Base-pair substitution: C677T base change causes a heat-labile MTHFR	PCR, restriction digestion	Homozygous C677T is risk factor for thrombophilia
Muenke nonsyndromic coronal craniosynostosis	FGFR3 4p16.3	Fibroblast growth factor receptor 3	Base-pair changes: unknown frequency	Sequence analysis	Inheritance pattern unclear

Mucopolysaccharidosis type 1, Hurler and Scheie syndromes	IDUA 4p16	Alpha-L-iduronidase	Assorted base-pair changes	Sequence analysis	Autosomal recessive inheritance
Multiple endocrine neoplasia, 2A	RET 10q11.2	RET oncogene	Mutations in exon 10 and 11 cysteine codons found in 95%	Sequence analysis	Autosomal dominant inheritance
Multiple endocrine neoplasia, 2B	RET 10q11.2	RET oncogene	Exon 16 M918T mutations found in 95%	Sequence analysis	Autosomal dominant inheritance
Multiple epephyseal dysplasia, dominant	COMP 19p13.1	Cartilage oligomeric matrix protein	COMP mutations account for 25% of MED	Sequence analysis	Autosomal dominant inheritance
	COL9A1 6q13	Collagen alpha 1(IX) chain	COL9A mutations account for <5% of MED		
	COL9A2 1p33-p32.2	Collagen alpha 2(IX) chain			
	COL9A3 20q13.3	Collagen alpha 3(IX) chain			
	MATN3 2p24-p23	Matrilin-3	MATN3 mutations account for 10% of MED		
Multiple epephyseal dysplasia, recessive	SLC26A2 5q32-q33.1	Sulfate transporter	Assorted base-pair changes	Sequence analysis	Autosomal recessive inheritance
Myoclonic epilepsy with ragged red fibers (MERRF)	MTTK gene of mtDNA	$tRNA^{Lys}$	Base-pair substitutions: A8344G: 80% T8356C and G8363A: 10% Others: 10%	Sequence analysis	Mitochondrial (maternal) inheritance
Myotonic dystrophy	DMPK 19q13.2-q13.3	Myotonic dystrophy protein kinase	Trinucleotide (CTG) repeat expansion	PCR, PAGE, Southern blot for large expansions	Allele expansion ranges: Normal: 5–37 Intermediate: 38–49 Mild: 50–150 Classical: 100–1500 Congenital: over 1000
NARP (Neurogenic muscle weakness, ataxia, retinitis pigmentosa)	MTATP6 gene of mtDNA	ATP synthase A6	Base-pair substitutions: MTATP6: T8993G or T8993C: > 50%	Sequence analysis	Other genes involved: MTTL1, MTTK, MTND1, MTND3, MTND4, MTND5, MTND6, MTCO3, MTTW, MTTV

(*continued overleaf*)

Table 1 (*continued*)

Disorder or syndrome	Gene, map location	Protein product	Mutation type(s): % detected	Diagnostic methods	Inheritance or mutation comments
Neurofibromatosis 1	NF1 17q11	Neurofibromin	Point mutations: ~ 80%	Protein truncation, Sequence analysis	Autosomal dominant inheritance; half of all cases are de novo mutations
			Gene deletions: 5–10%	FISH	
Neurofibromatosis 2	NF2 22q12.1	Merlin (Schwannomin)	Assorted base-pair changes detected in ~65%	Mutation scanning; sequence analysis	Autosomal dominant inheritance; half of all cases are de novo mutations
Noonan syndrome	PTPN11 12q24.1	Protein-tyrosine phosphatase, nonreceptor type 11	Assorted base-pair changes found in 50%	Sequence analysis	Autosomal dominant inheritance
Norrie disease	NDP Xp11.4	Norrin	Base-pair changes: 85% Submicroscopic deletions: 15%	Sequence analysis; Southern blot	X-linked recessive inheritance
Oculocutaneous albinism, type 1 (OCA1A and OCA1B)	TYR 11q14-q21	Tyrosinase	Assorted base-pair changes: OCA1 mutations completely inactivate TYR; OCA1B mutations partially inactivate TYR	Mutation scanning, sequencing	Autosomal recessive inheritance
Oculocutaneous albinism, type 2 (OCA2)	P Gene 15q11.2-q12	P Protein	Assorted base-pair changes: Common mutation: 2.7-kb deletion in Africans; A481T in Japanese; V443I in Europeans	Mutation scanning, sequencing	Autosomal recessive inheritance
Oculopharyngeal muscular dystrophy (OPMD)	PABPN1 14q11.2-q13	Polyadenylate binding protein nuclear 1	Trinucleotide (GCG) repeat expansion	PCR, PAGE	Expansion ranges: Normal: $(GCG)_6$ Dominant: $(GCG)_{8-13}$ Recessive: $(GCG)_7$
Pallister–Hall syndrome	GLI3 7p13	Zinc-finger protein GLI3	Assorted base-pair changes in 50%; common mutations 2023delG and 2012 delG	Sequence analysis	Autosomal dominant inheritance

Peroxisome biogenesis disorders, Zellweger syndrome	PEX1 7q21-q22	Peroxisome biogenesis factor 1	Common PEX1 mutations detect 80%: I700fs and G843D	Sequence analysis	Recessive inheritance; Research testing for PEX6, PEX26, PEX10, PEX12, PXMP3 (PEX2), PEX3, PEX13, PEX16, PXF (PEX19)
Peutz–Jeghers syndrome	STK11 19p13.3	Serine/threonine-protein kinase 11	Assorted base-pair changes: 73% with positive history 65% with negative history	Sequence analysis	Autosomal dominant inheritance
Pendred syndrome	SLC26A4 7q22-q31	Pendrin	Assorted base-pair changes: 75% detected common mutations: L236P, T416P, and 1001 + 1 G-to-A	Sequence analysis	Autosomal recessive inheritance
Phenylalanine hydroxylase deficiency, phenylketonuria	PAH 12q23.2	Phenylalanine hydroxylase	Panels of 4–15 common mutations detect 30–50%; Sequencing entire gene detects 99%	Mutation scanning; sequence analysis	Autosomal recessive inheritance
Polycystic kidney disease, autosomal dominant	PKD1 16p13.3-p13.12	Polycystin	Assorted base-pair changes in PKD1: 85%	Sequence analysis	Autosomal dominant inheritance
	PKD2 4q21-q23	Polycystin 2	Assorted base-pair changes in PKD2: 15%	Sequence analysis	Autosomal dominant inheritance
Polycystic kidney disease, autosomal recessive	PKHD1 6p21		Mutation detection rate: 40–80%	Mutation scanning; sequencing	Autosomal recessive inheritance
Prader–Willi syndrome	SNRPN, others 15q11.2-q13		Methylation abnormality: 99%	Southern blot Methylation-sensitive PCR	Deletions and UPD are usually de novo mutations; imprinting center defects are inherited as sex-limited autosomal dominant.
			Chromosome deletion: 70%	FISH	
			Uniparental disomy of chromosome 15: ~25%	Microsatellite analysis	

(*continued overleaf*)

Table 1 (*continued*)

Disorder or syndrome	Gene, map location	Protein product	Mutation type(s): % detected	Diagnostic methods	Inheritance or mutation comments
			Imprinting center defects: less than 5%	Southern blot Methylation-sensitive PCR	
			Chromosomal rearrangements: 1%	Karyotype FISH	
Prothrombin gene thrombophilia	Factor 2	Prothrombin	G20210A in 100%	PCR, restriction digestion	Population incidence: 2%
					In patients with deep vein thrombosis: 6%
PTEN Hamartoma tumor syndrome (PHTS)	PTEN 10q23.31	Dual-specificity phosphatase PTEN	Assorted PTEN mutations: Cowden syndrome: 80% BRRS: 60% Proteus-like syndrome: 50% BRRS: 11% PTEN deletion	Sequence analysis, quantitative PCR	Autosomal dominant inheritance
Retinitis pigmentosa, autosomal dominant (ADRP)	RHO 3q22.1	Rhodopsin	Accounts for 25–30% of ADRP	Sequence analysis	Autosomal dominant inheritance
	RDS 6p21.2	Peripherin 2	Accounts for 5–10% of ADRP		
	RP1 8q12.1	Oxygen-regulated protein 1	Accounts for 5–10% of ADRP		
	IMPDH1 7q32.1	Inosine monophosphate dehydrogenase 1	Accounts for 3–5% of ADRP		
	PIMIK 7p14.3	Pim-1 kinase	Unknown %		
Retinitis pigmentosa, autosomal recessive (ARRP)	RPE65 1p31.2	Retinal pigment epithelium-specific 61 kDA protein	Accounts for 2% of ARRP	Sequence analysis	Autosomal recessive inheritance
	ABCA4 1p22.1	Retinal-specific ATP-binding cassette transporter, retinal recessive	Rare		
	CRB1 1q31.3	Crumbs protein homolog 1	Rare		
	USH2A 1q41	Usherin	Accounts for 4–5% of ARRP		

	MERTK 2q13	C-mer protooncogene receptor tyrosine kinase	Unknown		
	SAG 2q37.1	S-arrestin	Rare		
	RHO 3q22.1	Rhodopsin	Rare		
	PDE6B, 4p16.3	Rod cGMP-specific 3′, 5′-cyclic phosphodiesterase alpha subunit	Accounts for 3–4% of ARRP		
	CNGA1 4p12	cGMP-gated cation channel alpha 1 subunit	Rare		
	LRAT 4q32.1	Lecithin reitnol acyltransferase	Unknown %		
	PDE6A 5q33.1	Rod cGMP-specific 3′, 5′-cyclic phosphodiesterase alpha subunit	Accounts for 3–4% of ARRP		
	TULP1 6p21.3	Tubby-related protein 1	Rare		
	RGR 10q23.1	RPE-retinal G protein-coupled receptor	Accounts for 10–20% ARRP		
	NR2E3 15q23	Nuclear receptor subfamily 2 group E3	Rare		
	RLBP1 15q26.1	Cellular retinaldehyde-binding protein	Unknown %		
	CNGB1 16q13	Rod cGMP-gated channel beta subunit	Unknown %		
Retinitis pigmentosa X-linked (XLRP)	RPGR Xq21.1	Retinitis pigmentosa GTPase regulator	Accounts for 70% or XLRP	Sequence analysis	X-linked dominant or recessive inheritance
	RP2 Xp11.2	XRP2 protein	Accounts for 8% of XLRP		
Retinitis pigmentosa mitochondrial	MTTS2 MtDNA	Mitochondrial sevine tRNA2	Rare	Sequence analysis	Mitochondrial (maternal) inheritance
Retinoblastoma	RB1 13q14.1-q14.2	Retinoblastoma-associated protein	Assorted base-pair changes detected in 70–75%	Sequence analysis	Autosomal dominant inheritance

(*continued overleaf*)

Table 1 (*continued*)

Disorder or syndrome	Gene, map location	Protein product	Mutation type(s): % detected	Diagnostic methods	Inheritance or mutation comments
			Submicroscopic deletions detected in 8%	FISH, Southern blot	
Rett syndrome	MECP2 Xq28	Methyl-CpG-binding protein 2	Assorted base-pair changes detected in 80%	Mutation screening, sequence analysis	Affects females only; 99% cases are de novo
Rothmund–Thomson syndrome	RECGL4 8q24.3	ATP-dependent DNA helicase Q4	Assorted base-pair changes detected in ~70%	Sequence analysis	RECGL4 mutations cause absent or truncated proteins
Rubinstein–Taybi syndrome	CREBBP 16p13.3	CREB-binding protein	35% with assorted base-pair changes; Microdeletions detected in 10%	Sequence analysis; FISH	Autosomal dominant inheritance
Smith–Lemli–Opitz syndrome	DHCR7 11q12-q13	7-dehydrocholesterol reductase	Assorted base-pair changes: Common mutations are intron 8 splice acceptor, W151X, and R404C	Sequence analysis	Autosomal recessive inheritance
Spinal and bulbar muscular atrophy (SBMA, Kennedy disease)	AR Xq11-q12	Androgen receptor	$(CAG)_n$ repeat expansions: Normal: up to 34 Intermediate: 35–37 Affected: 38 or more	PCR, PAGE	Autosomal dominant inheritance
Spinal muscular atrophy	SMN1 5q12.2-q13.3	Spinal motor neuron	Homozygous deletions of exons 7 and 8: 95% compound heterozygotes for deletions and point mutations: 5%	PCR and restriction digestion, Sequence analysis	Autosomal recessive inheritance
Spinocerebellar ataxia, type I	SCA1 6p23	Ataxin-1	$(CAG)_n$ repeat expansions: Normal: 6–44 Intermediate: 36–38 Affected: 39–91	PCR, PAGE	Autosomal dominant inheritance
Spinocerebellar ataxia, type II	SCA2 12q24	Ataxin-2	$(CAG)_n$ repeat expansions: Normal: up to 31 Affected: 32–200	PCR, PAGE	Autosomal dominant inheritance
Spinocerebellar ataxia, type IV	SCA4 16q22.1	Unknown	Unknown		Autosomal dominant inheritance

Spinocerebellar ataxia, type V	SCA5 11p11-q11	Unknown	Unknown		Autosomal dominant inheritance
Spinocerebellar ataxia, type VI	CACNA1A 19p13	Voltage-dependent P/Q-type calcium channel alpha-1A subunit	$(CAG)_n$ repeat expansions: Normal: up to 18 Intermediate: 19 Affected: 20–33	PCR, PAGE	Autosomal dominant inheritance
Spinocerebellar ataxia, type VII	SCA7 3p21.1-p12	Ataxin-7	$(CAG)_n$ repeat expansions: Normal: 7–35 Intermediate: 28–35 Affected: 36–300	PCR, PAGE	Autosomal dominant inheritance
Spinocerebellar ataxia, type VIII	SCA8 13q21	Unknown	$(CTG)_n$ repeat expansions: Normal: 15–50 Intermediate: 50–70 Affected: 71–800	PCR, PAGE	Autosomal dominant inheritance
Spinocerebellar ataxia, type X	SCA10 22q13	Ataxin-10	$(ATTCT)_n$ repeat expansions: Normal: 10–22 Affected: 280–4500	PCR, PAGE	Autosomal dominant inheritance
Spinocerebellar ataxia, type XI	SCA11 15q14-q21.3	Unknown	Unknown		Autosomal dominant inheritance
Spinocerebellar ataxia, type XII	SCA12 5q31-33	Phosphatase P2a regulatory subunit	$(CAG)_n$ repeat expansions: Normal: 7–31 Affected: 55–78	PCR, PAGE	Autosomal dominant inheritance
Spinocerebellar ataxia, type XIII	SCA13 19q13.3-q13.4	Unknown	Unknown		Autosomal dominant inheritance
Spinocerebellar ataxia, type XIV	PKC8 19q13.4-qter	Protein kinase C gamma	Unknown		Autosomal dominant inheritance
Spinocerebellar ataxia, type XV	SCA15	Unknown	Unknown		Autosomal dominant inheritance
Spinocerebellar ataxia, type XVI	SCA16 8q22.1-q24.1	Unknown	Unknown		Autosomal dominant inheritance
Spinocerebellar ataxia, type XVII	TBP, SCA17	TATA binding protein	$(CAG)_n$ repeat expansions: Normal: 25–42 Intermediate: 42–44 Affected: 46–63	PCR, PAGE	Autosomal dominant inheritance
Spondyloepiphyseal dysplasia tarda, X-linked	SEDL Xp22.2-p22.1	Sedlin	Assorted base-pair changes detected in 80%	Sequence analysis	X-linked recessive inheritance

(*continued overleaf*)

Table 1 (*continued*)

Disorder or syndrome	Gene, map location	Protein product	Mutation type(s): % detected	Diagnostic methods	Inheritance or mutation comments
Stickler syndrome	COL2A1 12q13.11-q13.2	Collagen alpha 1(II) chain	Unknown	Mutation scanning, sequence analysis	Autosomal dominant inheritance
	COL11A1 1p21	Collagen alpha 1(XI) chain	Assorted base-pair changes detected in ~70–80%		
	COL11A2 6p21.3	Collagen alpha 2(XI) chain	Unknown		
Transthyretin amyloidosis	TTR 18q11.2-q12.1	Transthyretin	Assorted base-pair changes detect 99%; common mutation is V30M	Sequence analysis	Autosomal dominant inheritance
Tuberous sclerosis complex	TSC1 9q34	Harartin	Mutations detected in 30% of familial cases	Sequence analysis	Autosomal dominant inheritance
	TSC2 16p13.3	Tubrnin	Mutations detected in 50% of familial cases		
Usher syndrome, type 1	USH1A 14q32	Unknown	2% Detected	Mutation scanning, sequence analysis	Autosomal recessive inheritance
	MYO7A 11q13	Myosin VIIa	60% Detected		
	USH1C 11p15	Harmonin	5% Detected		
	CDH23 10q21	Cadherin-23	10% Detected		
	USH1E 21q21	Unknown	Unknown		
	PCDH15 10q21	Protocadherin	Unknown		
	SANS 17q24	Sans	Unknown		
Usher syndrome, type 2	USH2A 1q41	Usherin	USH2A base-pair changes detected in 80%; Most common: 2299delG	Sequence analysis	Autosomal recessive inheritance
	USH2B 3p24 USH2C 5q USH2D	Unknown	USH2B type is rare; USH2C mutations account for 15%	Sequence analysis	
Usher syndrome, type 3	USH3 3q24	Usher syndrome type 3 protein	Unknown	Mutation analysis	Autosomal recessive inheritance

Von Hippel–Lindau syndrome	VHL 3p26-p25	Von Hippel–Lindau disease tumor suppressor	Assorted base-pair changes detected in >90%; some mutations confer genotype/phenotype correlations	Sequence analysis	Autosomal dominant inheritance; 80% inherited and 20% de novo mutations
Waardenburg syndrome, type 1	PAX3 2q35	Paired box protein Pax-3	Assorted base-pair changes: detected in >90%	Sequence analysis	Autosomal dominant inheritance
Waardenburg syndrome, type 2	MITF 3p14-p12.3	Microphthalmia-associated transcription factor	Assorted base-pair changes: detected in 10–20%	Sequence analysis	Autosomal dominant inheritance
Werner syndrome	WRN 8p12-p11.2	Werner syndrome helicase	Assorted base-pair changes detected in ~90%	Sequence analysis	Autosomal recessive inheritance
Wilms tumor	WT1 11p13	Wilms tumor protein	10–15% of Wilms tumor patients are inherited	Deletions, sequence analysis	A second Wilms tumor locus at 11p15 is suspected
Wilson disease	ATP7B 13q14.3-q21.1	Copper-transporting ATPase 2	Assorted base-pair changes; common mutations: H1069Q, R778L, H714Q, delC2337	Mutation scanning; sequence analysis	Autosomal recessive inheritance
Xeroderma pigmentosum	XPA 9q22.3	DNA-repair protein complementing XP-A cells	25% of patients with XP	Sequence analysis	Autosomal recessive inheritance: Complementation groups not listed (mutation percentage): XPE (rare), XPF (6%), and XPG (6%)
	ERCC3 2q21	TFIIH basal transcription factor complex helicase XPB subunit	Rare		

(*continued overleaf*)

Table 1 (*continued*)

Disorder or syndrome	Gene, map location	Protein product	Mutation type(s): % detected	Diagnostic methods	Inheritance or mutation comments
	XPC 3p25	DNA-repair protein complementing XP-C cells	25% of patients with XP		
	ERCC2 19q13.2-q13.3	FIIH basal transcription factor complex helicase subunit	15% of patients with XP		
	DDB2 11p12-p11	DNA damage binding protein 2	Rare		
XX male syndrome; XY gonadal dysgenesis	SRY Yp11.3	Sex-determining region Y protein	Assorted base-pair changes: detected in 80% of XXMS	Sequence analysis, FISH	XX male syndrome is de novo; XY; if SRY translocated onto an autosome, inheritance is sex-limited dominant

For each syndrome, the associated genes and their chromosomal map location, mutation detection rates and most methods, and inheritance patterns are listed, where known. This listing is not comprehensive due to space limitations, but focuses on the more common syndromes where molecular genetic testing is diagnostically useful (GeneTests, 1993-2004). Mutation-scanning techniques include heteroduplex analysis, SSCP, DGGE, DDGE, DHPLC, or CFLP. Deletions are detected by FISH (fluorescent in situ hybridization) or Southern blotting.

Specialist Review

The clinical and economic implications of pharmacogenomics

David L. Veenstra
University of Washington, Seattle, WA, USA

1. Introduction

The rapid advance of the Human Genome Project and the development of new genetic analysis technologies promise to bring a new era of genomics to medicine (Collins, 1999; Friend, 1999). Among the applications of genetics to medicine, pharmacogenomics will likely be one of the first tangible benefits from the Human Genome Project (Evans and Relling, 1999).

It has been suggested that the use of pharmacogenomics will be widespread and lead to overall decreased health care costs (Hodgson and Marshall, 1998; Kleyn and Vesell, 1998; Marshall, 1997; Persidis, 1998; Regalado, 1999; Sadee, 1999). However, this issue remains unclear. The objective of this article is to present a cost-effectiveness framework for evaluating the incremental clinical and economic benefits of pharmacogenomic-based therapies, apply this framework to noted pharmacogenomic examples, and evaluate the potential impact of pharmacogenomics on research and development in the pharmaceutical industry and the delivery of health care.

2. Economic evaluation of health care technologies

The integration of genetic technologies into medical practice will be a complex process (Holtzman and Marteau, 2000). Such an undertaking encompasses multiple technologies (molecular biology, informatics) and systems (pharmaceutical and health care industries), and society as a whole. Because of the different nature of using genetic information to improve patients' health, there has been increased interest in the broad-ranging impact of genomics – commonly referred to the ethical, legal, and social implications (ELSI). Although the implementation of pharmacogenomics will be guided by ethical and legal issues, it will be driven largely by economic factors – which are determined by a complex interaction of social utilities.

The impact of pharmacogenomics will be determined to a significant extent by incentives for researchers to develop targeted therapies, health care systems, and clinicians to provide them, and patients to accept them. Over the past several decades, economic evaluation in the health care field has evolved to study these questions. Drawing on methods and concepts from economics, clinical epidemiology, psychology, and the decision sciences, the field of "cost-effectiveness" research has synthesized a set of tools and a theoretical framework for evaluating the complex issues in health care (Garber and Phelps, 1997; Weinstein *et al*., 1996).

2.1. Types of economic evaluation

There are a variety of methods used in the economic evaluation of health care technologies: (1) cost-minimization, (2) cost-consequences analysis, cost-benefit analysis, (3) cost-effectiveness analysis, and (4) cost-utility analysis (Table 1). These methods vary primarily in the way drug effectiveness is valued. For example, in cost-minimization, it is assumed there is no difference in drug effectiveness. In both cost-effectiveness and cost-consequences analysis, effectiveness is measured in natural, clinical units such as heart attacks or infections avoided. In cost-benefit analysis, a monetary value is assigned to effectiveness (e.g., a heart attack might be "valued" at $100 000). And in cost-utility analysis, effectiveness is measured

Table 1 Types of economic evaluations in health care

Study design	Costs measured?	Effects measured?	Strengths	Weaknesses
Cost-minimization	Yes	No	• Easy to perform	• Only useful if effectiveness is assumed to be the same
Cost-consequences	Yes	Yes, typically in clinical terms	• Data presented in a straightforward fashion	• A ratio is not calculated, thus making comparisons of health interventions difficult
Cost-benefit	Yes	Yes, in economic terms	• Good theoretical foundation • Can be used within health care and across sectors of the economy	• Less commonly accepted by health care decision makers • Evaluation of benefits methodologically challenging
Cost-effectiveness	Yes	Yes, in clinical terms	• Relevant for clinicians • Easily understandable	• Cannot compare interventions across disease areas
Cost-utility	Yes	Yes, in quality-adjusted life years (QALYs)	• Incorporates quality of life • Comparable across disease areas and interventions	• Requires evaluation of patient preferences • Can be difficult to interpret

in quality-adjusted life years (QALYs), which account for improvements in both life expectancy and quality of life. Another characteristic that differentiates these methods is that cost-minimization and cost-consequences analysis do not involve the calculation of a ratio. Of note, although "cost-effectiveness analysis" is a specific type of economic evaluation (Table 1), the term also refers generally to all types of economic evaluation in health care.

2.2. *Cost-effectiveness calculation*

In any economic evaluation, it is important that the technology being evaluated is compared to current medical practice. Weinstein and Staason (1977) defined the incremental cost-effectiveness ratio (ICER) as

$$ICER = \frac{C2 - C1}{E2 - E1} \qquad (1)$$

where $C2$ and $E2$ are the cost and effectiveness of the new intervention being evaluated and $C1$ and $E1$ are the cost and effectiveness of the standard therapy. The costs and effects that are included in equation (1) depend on the perspective of the analysis. From a societal perspective, indirect costs and effects such as patient time away from work, downstream medical care costs years or decades after the intervention, and the quality of life of the patient and even their family need to be considered. Because of the all-encompassing nature of the societal perspective, it is generally best suited for national health care plans. More relevant to health care plans or providers in the United States is the payer perspective, which addresses primarily the direct medical care costs incurred by the payer (e.g., drug cost, professional fees, hospital stay).

Where are the data for cost-effectiveness calculations obtained? Because there is such diversity in the data requirements, it is unusual to obtain all estimates from one study. In some cases, cost-effectiveness studies can be based on a single randomized clinical trial. However, because clinical trials are usually in a controlled setting, the costs incurred are not representative of utilization in a real-world setting. The "efficacy" observed in a controlled setting can also be distinguished from the "effectiveness" that could be expected in practice. Finally, the time frame of clinical trials for chronic conditions are generally not sufficient to evaluate long-term outcomes. Because of these reasons, modeling techniques such as decision analysis are often used to extrapolate the results from clinical studies using primarily epidemiologic and economic data from other sources (Detsky *et al*., 1997).

2.3. *Cost-effectiveness criteria*

How can cost-effectiveness information guide health policy decisions? The favored approach for formal decision-making rules is to utilize cost-utility analysis because it allows for comparisons across interventions and diseases, accounts for impact on life expectancy and quality of life, and has theoretical foundations in welfare

economics. Medical interventions are considered to be cost-effective when they produce health benefits at a cost comparable to other commonly accepted treatments. A general guide is that interventions that produce one quality-adjusted life year (QALY, equivalent to 1 year of perfect health) for under $50 000 are considered cost-effective, those between $50 000 and $100 000 per QALY are of questionable cost-effectiveness, and above $100 000 per QALY is not considered cost-effective. The cutoff of $50 000 per QALY was derived loosely from the cost of providing dialysis for a patient for one year – a service paid for by Medicare for any US citizen.

2.4. *Strengths and weaknesses*

Cost-minimization has probably played the biggest role in drug-selection decisions in the past because it is the most straightforward approach, and decisions are often driven by drug budget impact. For the most part, this is unfortunate, as the assumption that different drugs have the same effect rarely holds true. Cost-benefit calculations are useful because the results are directly applicable to budget impact assessments, but the process of assigning monetary value to health is both technically and politically challenging. Clinicians are often more accepting of cost-effectiveness analysis because results such as "cost per heart attack avoided" seem intuitive; however, such calculations make evaluation across interventions and disease areas difficult (e.g., is it better to prevent a heart attack or a stroke?). Cost-utility analysis has been advocated because it measures benefit in patient-oriented terms (quality of life) and permits comparison between different interventions by standardizing the denominator. Cost-utility analysis works particularly well in settings with a single health care payer, as the overall objective of such a health care system is to improve society's health in a cost-effective manner. In the United States, however, health care plans are not structured to provide all-encompassing, lifetime health care, and cost-utility analysis does not fit easily within the decision-making framework. For this reason, many cost-effectiveness practitioners and health plans are relying more often on cost-consequences analysis, which presents economic and clinical information in an evidence-based format.

2.5. *Demand for economic information*

The application of cost-effectiveness analysis has increased dramatically in the past decade as a result of increasing health care costs and the desire to deliver the greatest health value for the money. The formal application of cost-effectiveness analysis to drug coverage decisions has its origins in countries with single-payer health care systems (e.g., government sponsored). Recently, multiple countries and health care systems have begun to adopt requirements for pharmacoeconomic information. These requirements formalize an otherwise implicit demand for health care technologies that are cost-effective, and will influence, to a certain extent, "go, no-go" decisions in drug research and development.

The United Kingdom, Canada, and Australia all have formal requirements in place for cost-effectiveness information and programs in place for evaluating cost-effectiveness data – the National Institute for Clinical Excellence (NICE, United Kingdom), the Canadian Coordinating Office for Health Technology Assessment (CCOHTA), and the Pharmaceutical Benefits Advisory Committee (PBAC, Australia) (CCOHTA, 1997; PBAC, 1999; NICE, 1999). To varying degrees, European countries other than the United Kingdom utilize economic analyses in decision making, and several countries such as The Netherlands have indicated that formal requirements will be introduced in the near future (Drummond *et al*., 1999). In Japan, the Ministry of Health and Welfare modified the guidelines for submission of pharmacoeconomic data were revised in September 1994 to include specific data requirements and submission format, although there has not been much response to this directive on the part of the pharmaceutical industry (Hisashige, 1997).

In the United States, cost-effectiveness information is most often used in support of drug formulary listing in managed care settings. Several managed care organizations and pharmacy benefits managers currently have or are considering the inclusion of guidelines that require outcomes and economic information for formulary evaluation (Langley, 1999; Mather *et al*., 1999). In addition, the Academy of Managed Care Pharmacy (AMCP) has recently adopted guidelines for the submission of information, including outcomes and cost-effectiveness data, to support formulary consideration (Fry *et al*., 2003).

2.6. Cost-effectiveness drivers

Although the determination of the incremental costs and effects of a new health care intervention can be complicated, the incremental cost-effectiveness of almost all interventions is usually driven by a few important factors: the cost and efficacy of the intervention, the morbidity, mortality, and prevalence of the disease that is being prevented, and the cost of treating the disease. On the basis of these factors, Veenstra and colleagues developed a cost-effectiveness framework for evaluating pharmacogenomic interventions (Veenstra *et al*., 2000a; Phillips *et al*., 2001a).

3. Cost-effectiveness framework

3.1. Economic costs

The cost of a genetic test will go beyond the procurement cost of the test itself, as with any diagnostic procedure. There will be induced costs, including direct costs such as additional medical care follow-up, and indirect costs such as patient time away from work. These costs are potentially of greater magnitude than the direct cost of purchasing the test. If test results are not available at the point of care, the additional clinical, administrative, and patient time required to respond to the test results may negate any efficiency gained by providing the test. For conditions such as acute infectious processes, a delay in obtaining test results may

have serious clinical consequences. In contrast, for chronic diseases, the availability of test results within a week's time frame may have only a minimal impact on overall treatment costs if additional office visits, and so on, are not required.

However, these induced costs will be offset to a certain extent. One of the benefits of pharmacogenomic testing is that the information can be used throughout the lifetime of the patient. For example, rather than measuring serum drug levels to infer the metabolic capability of a patient every time a novel drug is introduced to a patient, an assay to identify variations in the genes that encode drug metabolizing enzymes could be used throughout the lifetime of the patient, and for a variety of medications. The induced costs with pharmacogenomic testing also will likely be less than those associated with genetic testing for disease risk.

Finally, a cost that must be considered is the impact on patients of knowing information about their genetic makeup. Knowledge about genetic variations may lead to anxiety and a decreased quality of life in some patients, in addition to behavior such as avoiding all drug therapies. In contrast, patients without any major genetic variations may adopt a careless attitude with regard to drug compliance and consumption. Although initial work in the area of breast cancer (Lerman *et al*., 1996) suggests that patients benefit from knowledge of their genetic status, there is a critical need for additional studies in this area.

3.2. Effectiveness of genetic tests

As with data from controlled clinical trials, it is important to distinguish the "efficacy" of a genetic test from its "effectiveness". The efficacy of a test can be viewed as the diagnostic ability of the assay – that is, the ability of the test to accurately detect the genetic variation it was designed to identify. Diagnostic test performance is typically evaluated on the basis of sensitivity and specificity, or receiver-operator curves (ROCs). Because genetic tests have high sensitivity and specificity when direct sequencing or restriction site assays (>90%), they are often viewed as being highly accurate. But in a cost-effectiveness or clinical perspective, it is the prognostic significance of the test result that is important (its effectiveness).

The prognostic significance of a test is determined by the degree of association between the identified genetic variation and its physical manifestation(s). The association between genotype and phenotype, known as *gene penetrance*, will drive both clinical and economic outcomes. For example, if half of all patients with a gene variant experience a severe side effect from a drug (gene penetrance of 50%), avoiding the use of that drug in all patients with the variant would unnecessarily deprive the other half of the patients (the "false positives") of medication. The issue of "false-positives" will be important for almost all applications of pharmacogenomics, and the consequence of labeling patients as having a genetic variation despite the fact that not all of them will have clinically relevant effects must be considered. Genes with high penetrance will be better candidates for cost-effective pharmacogenomic strategies. Note that the term "false positives" does not refer to patients that were falsely identified as having a variant gene, but patients *with* a variant gene that do not express the clinical phenotype.

3.3. Outcomes: clinical and economic

Providing individualized drug therapy is an inherently appealing concept, and has driven much of the excitement about pharmacogenomics. The clinical and economic benefits of doing so, however, must be considered. In the case of pharmacokinetic strategies, avoiding adverse drug reactions (ADRs) will be the most likely benefit, as serious ADRs have been associated with significant morbidity, mortality, and economic costs. A recent analysis by Phillips *et al*. (2001b) suggests that genetic variations in drug metabolizing enzymes are associated with serious ADRs.

Testing costs for pharmacodynamic strategies, on the other hand, will be offset by avoiding unnecessary drug expenditures for patients who are unlikely to respond, or by providing beneficial treatment to patients that would otherwise not have been treated. Thus, pharmacodynamic-based strategies will likely be more cost-effective for expensive or chronic medications.

3.4. Drug monitoring and individualization

The *incremental* cost-effectiveness of pharmacogenomics will depend on the current ability to accurately monitor patients for toxic effects or drug response and individualize their therapy accordingly. Plasma drug levels are often used to monitor toxic drugs, while surrogate markers such as blood pressure for hypertension, lipid levels for hypercholesteremia, and HbA1c for diabetes are used to measure drug response for chronic diseases. When there are readily available, inexpensive, and validated means of monitoring drug response, pharmacogenomics may offer little incremental benefit.

3.5. Gene prevalence

Finally, the cost-effectiveness of any preventative screening strategies, such as pharmacogenomics, is highly dependent on the underlying prevalence of disease. In the case of pharmacogenomics, it is the frequency of the variant allele in the population being tested that will be a critical factor. For example, if the frequency of a variant allele is 0.5%, on average only one patient with a variant allele would be detected for every 200 patients tested. The importance of gene variant prevalence is highlighted in several of the examples below.

3.6. Summary of criteria

The considerations above provide a set of "cost-effectiveness criteria" for evaluating the potential cost-effectiveness of pharmacogenomics: (1) genetic factors – gene prevalence and gene penetrance; (2) test factors – sensitivity, specificity, and cost; (3) disease factors – severity of disease outcomes (clinical and economic); and (4) treatment factors – current ability to monitor drug response, cost of current therapy (Table 2). Prior to conducting a formal cost-effectiveness analysis,

Table 2 Factors that influence the cost-effectiveness of pharmacogenomic strategies

	Factors to assess	Features that favor cost-effectiveness
Gene	Prevalence	• Variant allele is relatively common.
	Penetrance	• Gene penetrance is high.
Test	Sensitivity; specificity; cost	• High specificity and sensitivity. • A rapid and relatively inexpensive assay is available.
Disease	Prevalence	• High disease prevalence in the population.
	Outcomes and economic impacts	• High untreated mortality. • Significant impact on quality of life. • High costs of disease management using conventional methods.
Treatment	Outcomes and economic impacts	• Reduction in adverse effects that significantly impact quality of life or survival. • Significant improvement in quality of life or survival due to differential treatment effects. • Monitoring of drug response is currently not practiced or difficult. • No or limited incremental cost of treatment with pharmacogenomic strategy.

Adapted from Flowers C and Veenstra DL (2000) Will pharmacogenomics in oncology be cost-effective? *Oncology Economics*, **1**, 26–33

these criteria can be useful indicators as to which interventions warrant a full cost-effectiveness analysis. These criteria also can assist scientists in designing basic research strategies that will be more likely to result in clinically useful and economically viable improvements in patient care. Below we review several examples of pharmacogenomics and evaluate their potential cost-effectiveness.

4. Examples

4.1. Pharmacodynamic-based strategies

4.1.1. Hyperlipidemia

A recent study reported the association of a variant allele of cholesteryl ester transferase protein (CETP), which is involved in cholesterol metabolism, with clinical response to pravastatin (Kuivenhoven *et al*., 1998). Drug response as measured by coronary vessel intraluminal diameter was correlated with CETP genotype, but not with lipid levels, suggesting that drug response may be predictable based on CETP genotype but not the typically used surrogate marker, lipid levels. This finding, if verified in subsequent long-term studies, could have a significant impact on the management of hyperlipidemia given that the prevalence of the non-responder genotype is 16%. Although the outcome of administering pravastatin to a nonresponder in the short term may simply be hyperlipidemia for a month or two,

traditional monitoring methods would not detect the lack of response, and in the long term the patient would be a increased risk of outcomes that are clinically severe and expensive (e.g., myocardial infarction), and expenditures on antihyperlipidemia agents would be significant as patients are often on therapy for decades.

4.1.2. HIV

Highly Active Anti-Retroviral Therapy (HAART) has resulted in dramatic reduction in HIV-related morbidity and mortality, but only 46% of patients are able to reach <50 copies/mL with 48 weeks of HAART (Hirsch *et al*., 2000). Most patients eventually "fail" initial therapy because of problems with drug adherence, drug toxicities, or virological resistance to HIV protease and reverse transcriptase inhibitors.

The evaluation of viral genotype appears to be clinically useful for individualizing HIV treatment cocktails in patients who have failed an initial regimen of HAART (secondary resistance). The Community Programs for Clinical Research on AIDS (CPCRA) trial 046 showed that among patients who failed HAART, viral suppression <500 copies/mL) with a subsequent regimen was significantly more common for patients randomized to receive genetic testing (34%) than for patients treated on the basis of clinical judgment alone (22%) (Baxter *et al*., 2000). The AntiretroVIRal ADAPTtation (VIRADAPT) trial reported similar results (Durant *et al*., 1999). These studies can be viewed as a "gold-standard" for the clinical evaluation of the effectiveness of pharmacogenomic testing strategies because patients were randomized to testing versus no testing, although long-term outcomes were not evaluated.

Several of the factors associated with HIV secondary resistance testing would suggest that it may be cost-effective: clinically severe and expensive outcomes for patients who fail HAART, identifying the drug(s) responsible for poor response is difficult, a genetic test is commercially available (approximately US$ 355), and the effectiveness of genotyping has been established in a pragmatic randomized trial. However, with regard to primary testing, the prevalence of resistance in treatment naive patients is fairly low, 1–10%, suggesting that primary resistance testing may be cost-effective only in higher-risk populations.

Weinstein *et al*. (2001) recently evaluated the cost-effectiveness of both primary and secondary HIV resistance testing using cost-effectiveness and decision-analysis techniques to model life expectancy, quality of life, and lifetime costs. The authors estimated that secondary resistance testing was cost-effective compared to no testing ($17 900 per QALY gained). The cost-effectiveness of primary testing was highly dependent on the prevalence of resistance in a treatment naive population: $22 300 per QALY at 20% prevalence and $69 000 per QALY at 4% prevalence. The results support current guidelines for the use of secondary testing, but additional studies are needed to evaluate the effectiveness of primary testing and elucidate the prevalence of HIV resistance in different settings.

4.2. Pharmacokinetic-based strategies

Many of the examples of pharmacodynamic-based strategies are preliminary and implementation in clinical practice may be years to decades in the future. In

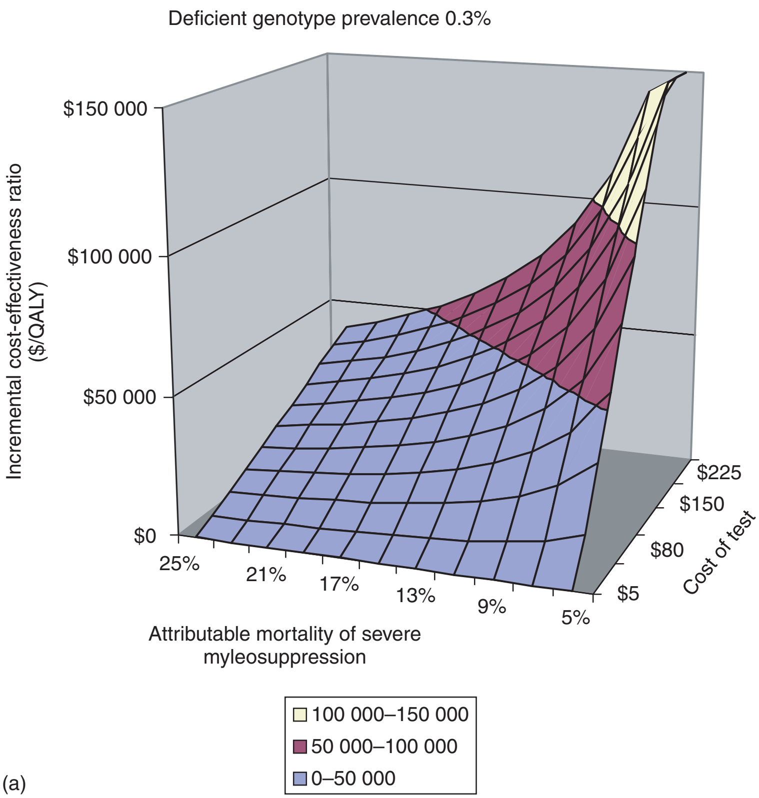
contrast, there has been extensive research on the genetic variation of enzymes involved in drug metabolism. Many of the first applications of pharmacogenomics will likely be in this area because of the extensive basic research conducted over the past several decades.

Adverse drug reactions are a significant cause of morbidity and mortality. Although many adverse drug reactions are considered "nonpreventable", pharmacogenomics may help to prevent these reactions. In a recent study, Phillips *et al*. (2003) evaluated the potential role of pharmacogenomics in reducing the incidence of adverse drug reactions. Using a systematic review of ADR studies and reviews on polymorphisms of drug metabolizing enzymes, the authors identified 27 drugs frequently cited in adverse drug reaction studies. Among these drugs, 59% were metabolized by at least one enzyme with a variant allele known to cause poor metabolism. Conversely, only 7–22% of randomly selected drugs is known to be metabolized by enzymes with this genetic variability ($p < .01$). These results suggest that genetic variability in drug metabolizing enzymes plays an important role in adverse drug reactions. Below, we review the potential cost-effectiveness of preventing ADRs from one of the drugs included in their study, the anticoagulant warfarin.

4.2.1. Warfarin

The anticoagulant warfarin exhibits large variability in drug response, primarily because of disease, diet, and drug interactions. However, part of the variability has been attributed to polymorphisms of the enzyme that metabolizes warfarin, the cytochrome P450 enzyme CYP2C9 (Rettie *et al*., 1994). Individuals who are deficient in CYP2C9 activity may be at a higher risk for severe bleeding episodes and require lower starting doses or more frequent monitoring. The use of genetic information may thus assist clinicians in initiating and monitoring warfarin dosing.

The prevalence of heterozygotes is relatively high, approximately 30%, but patients with a null genotype are rare (<1%). In addition, serious bleeding events are rare in patients followed in anticoagulation clinics because warfarin therapy is closely monitored and individualized. Genetic testing will have to facilitate this process in a cost-effective manner. Initial studies suggested an association between CYP2C9 genotype and bleeding risk (Aithal *et al*., 1999). However, a subsequent study failed to detect an association between CYP2C9 genotype and anticoagulation variability (Taube *et al*., 2000). Additional epidemiologic studies are needed before assessing the appropriateness of CYP2C9 genetic analysis for patients on chronic warfarin therapy.



4.2.2. Childhood leukemia

Because of their narrow therapeutic index, oncolytics will also be prime candidates for pharmacogenomics (Iyer and Ratain, 1998). An often cited example is dosage individualization for 6-mercaptopurine (6-MP), which is used for treatment of acute lymphoblastic leukemia (ALL) in children (Krynetski and Evans, 1999). Thiopurine *S*-methyltransferase (TPMT) is responsible for the inactivation of 6-MP, and TPMT

deficiency is associated with severe hematopoietic toxicity when deficient patients are treated with standard doses of 6-MP.

Because the implications of overdosing 6-MP are serious, and because of the significant costs involved in treatment of ALL, testing of children to establish their TPMT genotype may be cost-effective. Veenstra *et al*. (2000b) developed a decision analytic model to evaluate the potential cost-effectiveness of genotyping children before administering 6-MP. The authors assumed that patients not dying from myleosuppression had a quality-adjusted life expectancy of 10 years (10 QALYs), the cost of treating myleosuppression was \$5000, and the probability of severe myleosuppression for a patient deficient in TPMT was 90% without testing and 10% with testing. Three parameters representative of the dimensions that affect the cost-effectiveness of pharmacogenomics were varied: (1) *economic* (cost of test, \$5 to \$250), (2) *genetic* (allele frequency, 0.3, 0.5, and 1.0%), and (3) *clinical* (mortality of myleosuppression, 5–25%).

The importance of gene prevalence is immediately apparent (Figure 1). At a null allele genotype frequency of 1.0%, the incremental cost-effectiveness of genetic

(a)

Figure 1 (a) Influence of cost of genetic test and severity of clinical outcome on the hypothetical cost-effectiveness of TPMT genotyping with a deficient genotype prevalence of 0.3%. (b) Influence of cost of genetic test and severity of clinical outcome on the hypothetical cost-effectiveness of TPMT genotyping with a deficient genotype prevalence of 1.0%

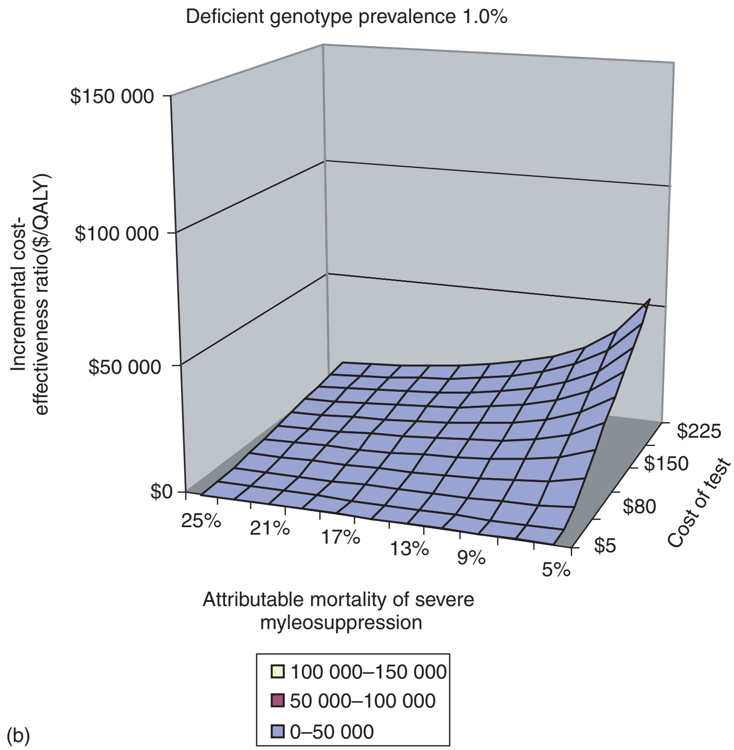


Figure 1 (*continued*)

testing falls below the commonly cited $50 000/QALY cutoff for essentially all of the parameter combinations tested. But for a frequency of 0.3%, the actual frequency of the null allele genotype for TPMT, the cost-effectiveness of genetic testing is not clear. In this scenario, the cost of the test has a significant impact on the cost-effectiveness ratio because approximately 300 children must be tested, on average, in order to identify the one that is TPMT deficient. However, with a high attributable mortality of severe myleosuppression (e.g., >20%), genetic testing is cost-effective for all scenarios.

5. Implications for the health care industry

5.1. Research areas

5.1.1. Adverse drug reactions

Drugs with a narrow therapeutic index will be some of the top candidates for individualization using pharmacogenomics. Drugs such as warfarin immediately come to mind, as well as oncolytics such as 6-MP. However, the widespread application of pharmacogenomics to prevent ADRs in the majority of currently marketed

drugs is less clear. Almost all drugs on the market have been developed for use in the general population. Drugs that have caused serious ADRs (e.g., seldane) – potentially as a result of genetic variation in drub metabolizing enzymes – have typically been removed from market. Thus, the incidence of serious ADRs related to genetic variation in drug metabolizing enzymes, although not known, may be low. Pharmacogenomics will thus be more cost-effective for secondary testing in patients that have had idiosynchratic ADRs as opposed to primary testing in the general population.

Where pharmacogenomics will play a more important role is in the development and approval of new drugs. The economic and clinical loss to society when a drug fails in the drug development stage because of rare, serious ADRs is significant. Through genetic profiling of the DMEs of patients enrolled in clinical trials, it will be possible to identify, to a certain extent, patients at higher risk for ADRs, and to achieve regulatory approval for the majority of patients who are able to metabolize the drug efficiently. Use of the drug in patients with poor metabolism would not necessarily be contraindicated, as appropriate dosage adjustments could be made.

5.1.2. Chronic diseases

The cost-effective application of pharmacodynamic-based strategies to chronic diseases such as hypertension, diabetes, and hypercholesteremia will depend on one critical aspect – the validity of the surrogate markers that are commonly used to measure disease progression and drug response (Temple, 1999). For example, pharmacogenomics may be useful for the treatment of hypertension. Clinicians are able to adjust dosing and modify drug selection on the basis of blood pressure response and side effects over the span of several office visits. However, recent studies suggest that blood pressure control may not be a good surrogate marker for clinical outcomes (Pahor *et al*., 2000; ALLHAT, 2000). In the ALLHAT study, treatment with doxazosin was terminated early because of a significantly higher incidence of combined cardiovascular disease events in patients on doxazosin compared to the diuretic chlorthalidone, even though higher systolic blood pressure was only 3 mmHg higher in the doxazosin group.

The outlook for diabetes, in contrast, is not as clear. Several studies have established the correlation between HbA1c levels and the complications of diabetes such as neuropathy, nephropathy, and retinopathy. However, with the classes of agents being introduced that work through a variety of mechanisms, it may be more difficult to rely on HbA1c as a surrogate marker in the future. Pharmacogenomics also may be cost-effective for disease states such as asthma, where outcomes are acute and expensive (e.g., emergency room visits), and attaining control of symptoms can be a trial and error process, and clinicians now have a multitude of drug therapies to choose from (Liggett, 1998; Israel *et al*., 2000). As more therapeutic alternatives become available for many disease states, pharmacogenomics will become increasingly important to assist in drug selection.

Drugs for which it is difficult to measure response in a relatively short time frame (e.g., 1 month) are also good candidates for individualization (Rioux, 2000). For example, patients can require up to 6 weeks of treatment before responding to antidepressant therapy (Jonsson *et al*., 1998). Another example is Alzheimer's

Disease – it is difficult to measure clinical response, and if no improvement or slowing of progression is seen over 6 months to 1 year, valuable time may be lost if other medications are available (Farlow *et al*., 1996; Poirier, 1999).

5.1.3. Nonhost genomics

The application of genomic analysis to infectious agents and tumor cell lines offers a useful "bridge" from traditional means of individualizing drug therapy to pharmacogenomics. Although the viral genome is analyzed rather than the patient's, many of the issues will be similar. Antibacterial sensitivity analysis is routinely used throughout the world to guide antibiotic drug selection. As genetic testing for HIV resistance exemplifies, analysis of viral genomes will likely become more commonplace and analogous to antibiotic sensitivity testing.

The use of genetic testing to identify viral genotype in the treatment of hepatitis C with interferon and ribivirin (combination therapy) provides an excellent case study in pharmacodynamic-based testing strategies. Patients with viral genotype 1 respond significantly better to 48 weeks of treatment versus 24 weeks of treatment, while patients with nongenotype 1 respond similarly to 24 or 48 weeks of therapy (McHutchinson *et al*., 1998). Several studies suggest that it is cost-effective to perform such testing. Younossi *et al*. (1999) reported that genotyping was the most cost-effective strategy among a variety of treatment options. Veenstra *et al*. (2000b) estimated that genotyping added 0.33 QALYs per patient compared to empiric 6-month therapy, at an incremental cost-effectiveness ratio of $3500/QALY. Thus, pharmacogenomics results in treating some patients for an extended duration, but in a cost-effective manner.

Pharmacogenomics may not play as significant a role in the analysis of bacterial genomes, as current phenotypic tests are readily available. However, a genomic analysis that would allow clinicians to prescribe appropriate therapy at the point of care would be an immense improvement over current practices of empirical antibiotic drug therapy.

Flowers and Veenstra (2000) reviewed the potential cost-effectiveness of pharmacogenomics in oncology. As noted above, there is a real and current need for individualized drug dosing in oncology. In addition, evaluation of tumor cell line genetics will become increasingly important as predictors of drug response are identified.

5.1.4. Minority populations

Another consideration is the desire to provide appropriate drug therapy to minority populations. To understand the impact of pharmacogenomics on minority populations, it will be necessary to understand two issues. First, will minority populations benefit clinically from pharmacogenomics? A recent study reported that enalapril is associated with a significant reduction in the risk of hospitalization for heart failure among white patients with left ventricular dysfunction, but not among similar black patients (Exner *et al*., 2001). Another consideration is the safety of pharmaceuticals. Minorities have not always been well represented in clinical trials, and thus may be at higher risk for ADRs because of

differences in genetic makeup, particularly with regard to the drug-metabolizing enzymes. If future studies indicate that pharmacogenomics can benefit minority populations, cost-effectiveness considerations may guide whether such strategies are pursued.

5.2. Incentives for research investment

What are the implications of pharmacogenomics for the pharmaceutical and biotech industries? The promise of new drug targets, decreased development time and cost, and quicker FDA approval all suggest that the integration of genomics with drug therapy will offer multiple opportunities for investment in research and development. But a key issue must be faced: will decreased market sizes with individualized drugs be offset by better market penetration and added value?

If we examine the interaction between CETP genotype and pravastatin, we can see how economic incentives might drive the development of targeted drug therapies. Suppose a company wished to develop and market a drug specifically for patients with the $\beta2\beta2$ genotype. Assume the captured market share is all patients with the $\beta2\beta2$ genotype, the effectiveness of the drug compared to nontargeted therapy is the inverse of the prevalence of the $\beta2\beta2$ genotype (i.e., if 50% of the population are non-responders and are eliminated, the drug's effectiveness will essentially be doubled), and the annual cost of standard therapy is $1000.

We examine three scenarios: (1) drug price remains unchanged regardless of effectiveness; (2) drug price is a function of effectiveness, so that the incremental cost-effectiveness ratio is constant; and (3) drug price is some unknown function of effectiveness (and gene prevalence). In the first scenario, total revenue is a linear function of gene prevalence (Figure 2a). In this instance, the only incentive for the development of a pharmacogenomic test is if the gene prevalence is higher than the company's current market share. In the second scenario, there is neither incentive nor disincentive for the development of individualized therapy – because companies can demand higher prices for better drugs, the decrease in market share is offset (Figure 2b) However, neither fixed drug prices nor drug prices that are a solely a function of cost-effectiveness are realistic. More likely is a scenario in which high prices can be charged for very effective medications that target a select few patients, but not sufficiently to generate the equivalent revenue from a larger market share (Figure 2c). In addition, as genotype prevalence approaches 100%, any gain in revenue from drug price would likely be lost in the extra development cost. Thus, we are left with a situation in which the most likely targets for pharmacogenomics are genetic variants that are neither too rare (e.g., $<10\%$) nor too common (e.g., $>90\%$) (Lindpainter, 1999).

Society's willingness to pay for individualized drug therapy potentially will be one of the most important factors driving or inhibiting the transition of pharmacogenomics from the laboratory to clinical practice (Lichter and Kurth, 1997; Danzon and Towse, 2002). In one of the first articles to quantitatively examine the potential impact of pharmacogenomics on health care payers and the pharmaceutical industry, Danzon and Towse concluded that the increased social gain from targeted therapy will need to be reflected in the value of pharmacogenomic-based drugs, and that

for drugs targeted to small populations, regulatory incentives such as the Orphan Drug Act may be needed to encourage investment in research and development.

Another potential benefit of pharmacogenomics to the industry is the opportunity for drug salvage – that is, obtaining approval for drugs that have been pulled from the market because of adverse events. Danzon and Towse examined the potential salvage of the drug Centoxin. Centoxin was developed to treat gram-negative bacteremia sepsis, which comprise one-third of all sepsis cases. However, Centoxin can cause harm to patients with non-gram-negative bacteremia and was withdrawn from the market. The authors calculated that if a (hypothetical) test had been developed to identify patients who would benefit from Centoxin, the test, surprisingly, could have cost $11 000 and still been cost-effective.

Figure 2 Effect of genotype prevalence on revenue generated for three pricing assumptions: fixed pricing, cost-effective pricing, and "real-world" pricing

5.3. Health care systems

Health care systems will also face significant challenges incorporating pharmacogenomics into health care delivery. In the short term, pharmacogenomics likely will lead to increased drug budgets because of higher drug prices and increased drug utilization (driven in part by patient demand), as well as increased diagnostic test costs. Because of these challenges, health care plans and payers should be prepared to evaluate the clinical and economic value of pharmacogenomic testing in a systematic and evidence-based fashion. Pharmacogenomics will necessitate improved clinician and patient education, more complex drug formulary structures, and advanced information systems at the point of care and drug dispensing. Despite these challenges, pharmacogenomics will offer health plans a mechanism for improving appropriate drug utilization, long-term improvement in their patients' health, and economic cost offsets in the future.

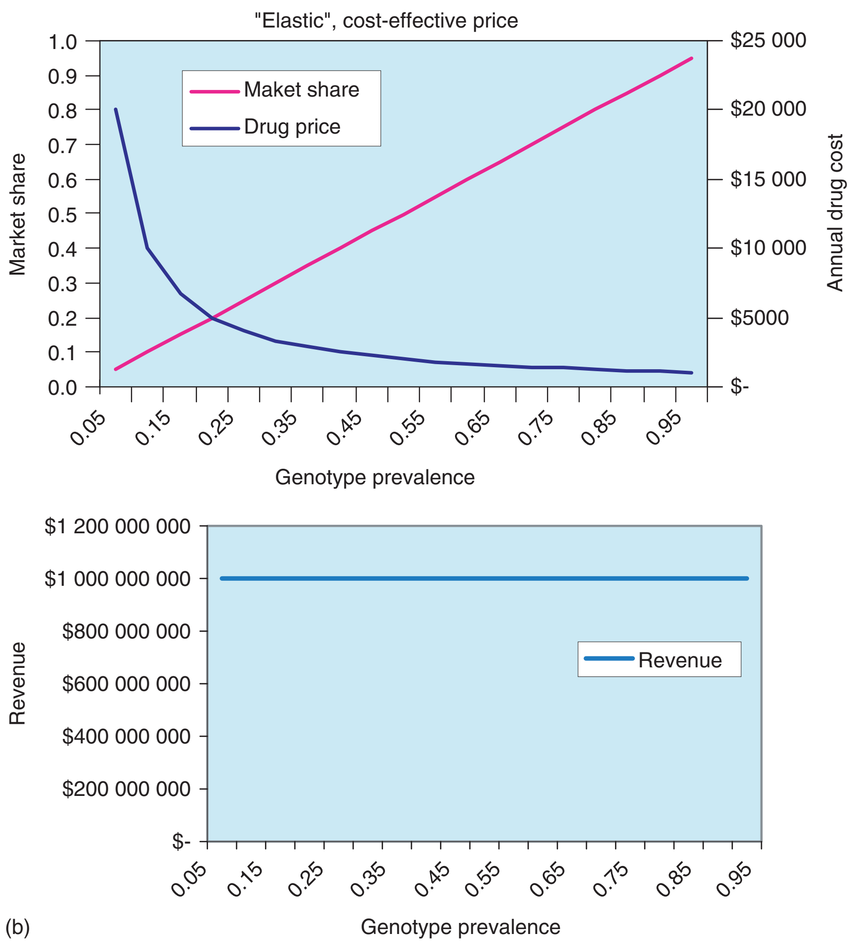

Figure 2 (*continued*)

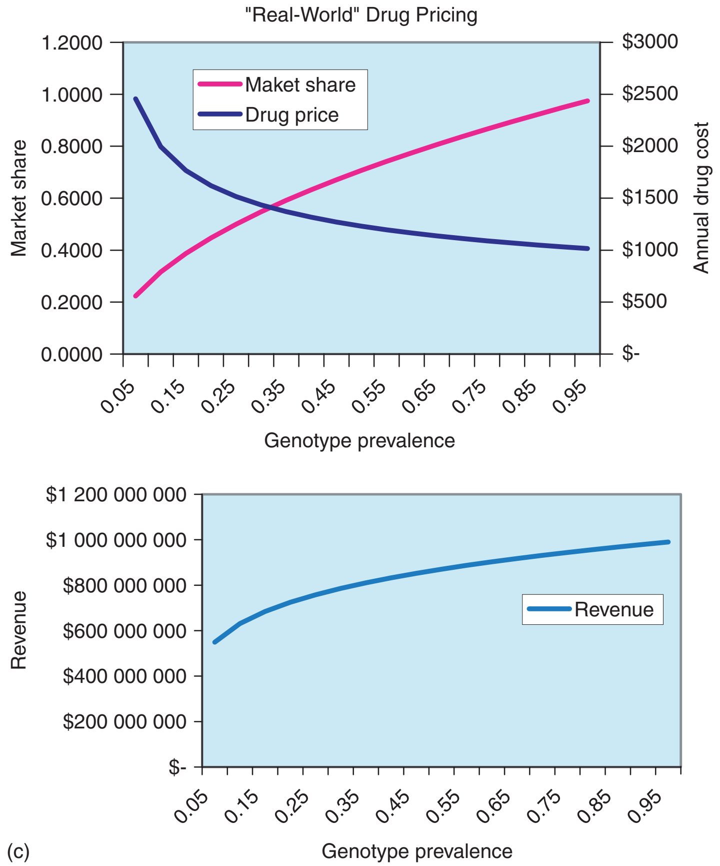

Figure 2 (*continued*)

6. Conclusion

The use of pharmacogenomics to individualize drug therapy will offer clinical and economic benefits. However, these benefits must be weighed against the additional cost of genotyping all patients in order to adjust therapy in a few. Our analysis suggests that pharmacogenomics will likely be cost-effective only for certain combinations of disease, drug, gene, and test characteristics, and that the cost-effectiveness of pharmacogenomic-based therapies needs to be evaluated on a case-by-case basis. Cost-effectiveness analysis can help scientists, clinicians, and decision makers invest in technologies and develop drug utilization guidelines that will benefit patients in an economically viable fashion.

Short Specialist Review

Molecular dysmorphology

Leslie G. Biesecker
National Institutes of Health, Bethesda, MD, USA

1. The origins of dysmorphology

Dysmorphology is defined as the study of abnormal form, typically in humans. It is the study of abnormal human embryonic development that can lead to major anomalies (those that impair health or require surgical correction) or minor anomalies (such as a low-set ear or mildly curved fifth finger). Clinical dysmorphology is a subdiscipline of clinical genetics. It is practiced by detailed clinical evaluation of patients to catalog their physical features such as cranial shape, eye position and shape, ear configuration, and dozens of other physical assessments, and these morphological data are integrated with functional assessments such as mental retardation, renal function, and so on, to form a global assessment of an individual. These attributes are then matched to clinical references (Cohen, 1997; Jones, 1997; Guest *et al*., 1999; Gorlin *et al*., 2001) to determine if the findings in the patient are sufficiently similar to a previously recognized malformation syndrome. The roots of the discipline arose around the beginning of the twentieth century in Germany, but with the collapse of German science after World War II, this discipline lay dormant until it was reactivated in the 1960s. This reactivation was pioneered by Robert Gorlin, John Opitz, David Smith, and Josef Warkany. During this phase, the primary activity was the clinical delineation of discrete pleiotropic disorders of human development, known as *birth defect* or *malformation syndromes*. Hundreds of these disorders were described that could be diagnosed clinically but only a handful were associated with etiologic factors such as chromosomal aberrations (*see* Article 11, **Human cytogenetics and human chromosome abnormalities**, Volume 1, e.g., Pallister–Killian syndrome) or environmental exposures (e.g., fetal alcohol syndrome). A large number of syndromes were inherited as simple Mendelian traits, but the technology did not exist to identify the genes that were mutated in those disorders.

2. Coupling genomics to dysmorphology

One technologic advance that facilitated the rapid dissection of the molecular basis of single gene dysmorphic syndromes was the conceptual development of positional cloning and the resources of the Human Genome Project (*see* Article 23, **The technology tour de force of the Human Genome Project**, Volume 3).

The existence of familial Mendelian dysmorphic syndromes allowed the meiotic mapping of the loci for these disorders and positional cloning of mutations in genes (*see* Article 9, **Genome mapping overview**, Volume 3). The determination that these genes were mutated in humans with dysmorphic syndromes implicated the genes as being necessary for normal development and coupled human clinical dysmorphology to developmental biology. This fusion of disciplines has been termed *molecular dysmorphology*, and it has facilitated rapid advances in the understanding of the molecular basis of normal and abnormal development (Epstein *et al*., 2004).

3. Utility of molecular dysmorphology

The morphology and pathology of humans has been studied in more detail than any other organism (Arguably, *Caenorhabditis elegans* may exceed the human because the fate and origin of every cell in the organism has been determined. However, the functional consequences of abnormal development are not nearly so detailed.). A by-product of intense and sophisticated human medical care is the cataloging of enormous amounts of clinical data on functional and anatomic variants. In contrast to the situation in the human is the situation with the mouse. Although there are many mouse mutants and the genetics of mouse breeding and transgenesis are very powerful (*see* Article 38, **Mouse models**, Volume 3), the phenotypic data are generally much weaker than in the human. This problem is most evident in human disorders that cause mental retardation or other functional disorders of the CNS (central nervous system). In a number of cases, it has been very difficult to characterize the CNS dysfunction in mouse mutants or knockout models. For these reasons, human phenotypic and positional cloning efforts have been coupled to complementary studies in animals where the genetics and other experimental parameters can be manipulated and controlled (*see* Article 37, **Functional analysis of genes**, Volume 3).

4. Examples of the power of molecular dysmorphology

Vertebrate limb development is an attractive system because it is relatively simple compared to some other organ systems (e.g., the CNS) and accessible to study. Major limb anomalies include limb reduction defects and limb duplications such as polydactyly. There are more than 100 heritable disorders that include polydactyly, either isolated or syndromic forms (Biesecker, 2002). Although each of these disorders is rare, as a group, the affected patients are frequently encountered in clinics and wards. Complementing the need for improved understanding of the medical causes and care of patients with limb anomalies is the opportunity to discover basic mechanisms of limb development. This opportunity drives the research on the molecular etiology of birth defects and there are many examples of successes. We have studied a group of disorders with a rare form of polydactyly, central polydactyly (Winter *et al*., 1993). This form of polydactyly occurs in

at least five different syndromes but interestingly has never been reported as a nonsyndromic form of polydactyly. The implication of this is that the genes that are involved in central digit specification are all likely to be part of a coordinated genetic pathway and because they are pleiotropic, are also critical for the development of other organ systems. We began by studying Pallister–Hall syndrome, which includes central polydactyly, bifid epiglottis and cleft larynx, imperforate anus, pulmonary segmentation anomalies, and hamartoma of the hypothalamus (Biesecker and Graham, 1996). It is inherited as an autosomal dominant trait, and the causative mutations were positionally cloned in 1997. The causative gene is the *GLI3* transcription factor, and all patients with PHS have mutations that predict production of truncated forms of the protein (Kang *et al*., 1997). This demonstrated that PHS was allelic to the Greig cephalopolysyndactyly syndrome (GCPS), which manifests polydactyly of the thumb/great toe or fifth digits, wide-spaced eyes, and macrocephaly (Vortkamp *et al*., 1991). A wide variety *GLI3* mutations cause GCPS. By comparing *GLI3* to its *D. melanogaster* homolog, *cubitus interruptus (ci)*, a hypothesis was developed regarding the basic biology of the human gene. Intriguingly, *ci* was known to be proteolytically processed into two forms, an activator and repressor form, but this was only known to occur in *Drosophila* (Aza-Blanc *et al*., 1997). Because all PHS mutations predicted truncated proteins that were similar to the processed repressor form of the ci protein, the prediction was made that GLI3 was similarly processed in mammals (Biesecker, 1997). The processing of GLI3 was subsequently described in mice (Wang *et al*., 2000) and is essentially certain to also occur in humans, because of evolutionary conservation.

There are many other examples of disorders where the positional cloning of the human gene led to important biological insights. These have included the fibroblast growth factor receptors in skeletal dysplasias and craniosynsotoses (Cohen, 2002; Wilkie *et al*., 2002), filamins A and B in at least seven dysmorphologic syndromes and skeletal dysplasias (Robertson *et al*., 2003; Krakow *et al*., 2004), PAX6 in aniridia, Peter's anomaly, other eye anomalies, and CNS malformations (van Heyningen and Williamson, 2002), and there are many other examples. These successes are impressive but must be regarded only as a first step. After the identification of the causative mutations, critical follow-up studies include detailed phenotype–genotype studies to determine if the patterns and types of mutations reveal more about the biology of the gene. In addition, the human data are then used to develop new scientific questions that can then be tested either by additional human studies, or more commonly, by moving into appropriate animal model systems such as the mouse, zebrafish, chicken, fruit fly, and so on.

In summary, molecular dysmorphology is a scientific approach to the study of human malformations that is a piece of the large scientific mosaic that needs to be assembled to develop a full understanding of the biologic and medical aspects of malformation syndromes. It couples the power of genomics and positional cloning with detailed phenotypic assessments of variations in human form. When coupled with complementary studies in animal model systems, molecular dysmorphology can be a crucial tool to understand the molecular basis of vertebrate developmental biology.

Short Specialist Review

Changing paradigms of genetic counseling

Katherine A. Schneider
Dana-Farber Cancer Institute, Boston, MA, USA

Vickie Venne
Huntsman Cancer Institute, Salt Lake City, UT, USA

1. Introduction

Genetic counseling, as a medical specialty, has been around since the 1970s, and like most things that have been around that long, the profession has undergone major evolution. This article will provide an overview of genetic counseling providers and services, with a focus on the profession's current "face".

2. Genetic counseling providers

The first genetic counseling providers were physicians, mostly pediatricians who cared for babies with congenital anomalies. With the onset of prenatal testing in the 1970s and the increased number of molecular tests available in the 1990s, overwhelmed physicians came to rely on allied health professionals to provide genetic counseling. Today, the typical genetic counseling provider has a Master of Science (MS) degree from an accredited genetic counseling training program and has passed a certification exam by the American Board of Genetic Counseling (ABGC). Currently, there are over 30 genetic counseling training programs in North America, as well as programs in England and Australia. Two states (Utah and California) have passed legislation to issue state licenses to genetic counselors and licensure is actively being sought in at least 15 other states. Other health care professionals who provide genetic counseling include geneticists, with either MD or Ph.D. degrees, and nurses with special training in genetics.

Almost all practicing genetic counselors in the United States belong to The National Society of Genetic Counselors (NSGC), a membership organization of about 2000 members. Affiliate professional organizations include the American Society of Human Genetics, American College of Medical Genetics, Canadian Association of Genetic Counselors, and the International Society of Nurses in Genetics. Genetic counselors also have close relationships with consumer support organizations, especially the Alliance for Genetic Support Groups.

3. Genetic counseling settings

In the 1970s, fewer than 10 training programs graduated genetic counselors, who then went on to work primarily in prenatal and pediatric genetic clinics at a few select medical centers. Today, genetic counselors are working in all 50 states and Canadian provinces and can be found in clinical settings as well as in educational, policy, research, administrative, biotechnology, and laboratory settings. Genetic counseling services are offered at almost all major medical centers, in satellite clinics, and in some private physician practices.

Genetic counselor job opportunities have changed dramatically over the past 10 years. In addition to the growing number of positions that do not involve direct clinical care, there is also a shift from prenatal and pediatric jobs to multiple different specialty areas. Similar to other medical providers, clinical genetic counselors are becoming increasingly specialized in areas as diverse as teratology, assisted reproductive technology, behavioral disorders, and adult-onset disorders. The most rapidly expanding job market for clinical genetic counselors is in the area of adult-onset disorders, specifically neurology, heart disease, and cancer. For more specific information about cancer genetic counseling, please refer to Article 88, **Cancer genetics**, Volume 2.

4. Indications for genetic counseling referrals

In the 1970s, most genetic counseling referrals were clients with prenatal or pediatric concerns. Genetic counseling referrals now occur at any point of life, from preconception or prenatal counseling through pediatric and adolescent years to adult-onset disorders. Individuals are referred to genetic counselors because of concerns about their own future health or the health of their offspring. Referrals can be triggered by the recognition of features or symptoms in a client, a pattern of disease within the family tree (pedigree), or a prospective parent's age or ethnicity. Genetic counseling clients have often been referred by a physician, although clients are increasingly self-referred.

5. Components of genetic counseling sessions

In 1975, the American Society of Human Genetics published a formal definition of genetic counseling as a communication process dealing with issues of occurrence, or risk of occurrence of a genetic condition (American Society of Human Genetics Ad Hoc Committee on Genetic Counseling, 1975). Over time, this definition has been adapted to include: (1) identifying a genetic condition, (2) explaining the inherited component to the client, (3) evaluating the client's options for action, (4) helping the client make a decision, and (5) supporting the client before, after, and during the process.

Historically, genetic counselors followed a nondirective counseling style. In this model, a counselor does not make direct recommendations to clients, but rather

helps them make the decision by presenting the pros, cons, and logistics of various options. Many genetic counselors are currently advocating for a change to a "shared decision-making" or "clients as partners" model, which is a more accurate reflection of current genetic counseling practices.

Genetic counseling services are best conducted as face-to-face interactions, although adjunct services include the use of CD-ROMs and Internet-based resources, group counseling, and telephone-based interactions. As telemedicine and Web-based learning becomes incorporated into the genetic counseling repertoire, the challenges will be how to obtain reimbursement for services, avoid potential provider liability, and still maintain close rapport with clients.

Genetic counseling sessions vary greatly depending on the specialty area. General components include: collection of the personal, pregnancy, and family history; risk assessment; description of potential genetic syndromes or heritable component of the condition; discussion and arrangement of genetic testing or medical management options; and counseling to help adapt to the choices, condition, and other familial issues that arise.

Collecting family history: The goal of pedigree collection and analysis is to determine if there is a pattern of disease in the family consistent with an inherited condition. Depending on the reason for the referral, genetic counselors typically collect health information about relatives over three to four generations. The information is diagrammed in a pedigree (Figure 1) and includes information about current ages or ages at death, presence of major health problems or diagnoses, pregnancy histories, and ethnicity.

Risk assessment: On the basis of information obtained from the family history (and often confirmed by medical records), the genetic counselor will discuss the likelihood that the client has a hereditary condition or is at risk for having a child with a genetic disorder. Some families will receive reassuring information, while those that do have a high likelihood of an inherited disorder will then receive additional information and support.

Description of genetic syndrome: Clients are educated about the hereditary condition, including the inheritance pattern, associated health and mental findings, the natural course and variability of the condition, and medical management issues, including procedures that are likely to be needed as well as screening and prevention options.

Genetic testing: Genetic testing is currently available for hundreds of inherited conditions, and includes cytogenetic, biochemical, and molecular analysis. Genetic testing can occur in prenatal settings, as part of an evaluation of a child or adult with a genetic condition, or be offered to adults worried about their predisposition of developing a specific condition in their family. A discussion about genetic testing includes the possible test results, the implications of the test result to the patient and other family members, the pros and cons of testing, and logistics of how testing would be done, including the cost of the analysis and when results will be available. Certain genetic tests may be available only from research laboratories. Individual results cannot be given to clients without confirmation from a clinically certified (CLIA approved) laboratory.

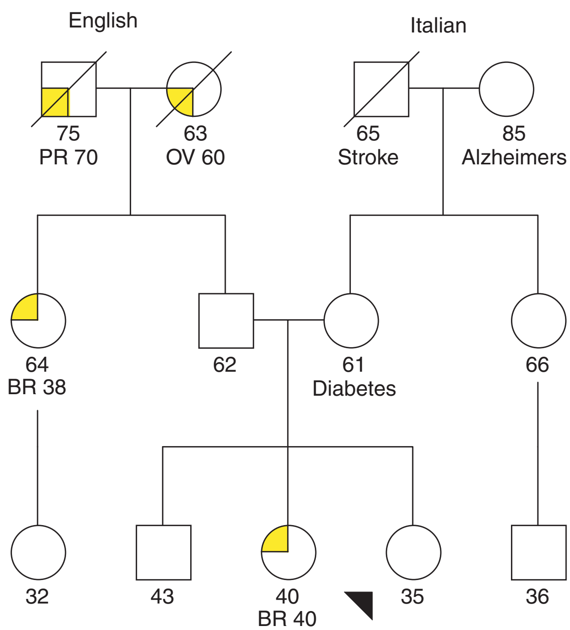

Figure 1 Example of a Genetic Counseling Pedigree. This is a 3-generation family tree depicting a family history of breast and ovarian cancer. Note that squares are men and circles are women. Current age or age at death is also noted. (Diagonal lines indicate people who are deceased.) The client (proband) is indicated by the arrow. Each cancer diagnosis and age at onset are indicated underneath the affected relative and the quadrants are shaded according to the general cancer type: upper left quadrant – breast cancer; lower left – genitourinary cancers; lower right – gastrointestinal cancers; and upper left – all other cancer types. In terms of this case example, the shaded circles and squares illustrate personal histories of breast cancer in the proband's sister and paternal aunt, ovarian cancer in the paternal grandmother, and prostate cancer in the paternal grandfather

Most clinical genetics programs require one to two additional counseling visits to arrange for testing and then to disclose and counsel about the result.

Counseling: During any consultation, genetic counselors will assess the psychological ability of the individual and/or family to cope with the information and management or testing choices that are being discussed. Family and social networks that can be used to support both the genetic counseling/test/diagnostic process and the natural history of the diagnosis are also identified. Genetic counselors use coping strategies, decision-making models, and other mechanisms to help clients adapt to the diagnosis or high-risk status.

6. Genetic counseling complexities and special issues

Most genetic conditions are rare, and family members become the medical experts regarding their condition. They may find themselves in the uneasy position of

having to describe the syndrome to their health care providers. Although this situation also occurs in other medical specialties, it is only one of the issues unique to or more intensified in the world of genetic counseling. This section illustrates some of the interesting family dilemmas and difficult ethical situations surrounding genetic counseling and testing.

Genetic conditions are a family affair: The identification of a genetic condition can send a ripple effect through the family as the awareness of risk spreads. Certain family members will be at risk while others will not, a fact that can seriously strain family relationships. Genetic test results may exacerbate communication problems in families that are already dysfunctional or who operate with secretive or deceptive communication styles. Situations may also arise in which one family member wants genetic testing information but other relatives do not. Or perhaps a person with a positive genetic test refuses to divulge risk information to his/her adult offspring despite potential consequences for their health. Clients may worry about their obligations to disclose genetic test results to other family members. Individuals need to balance the importance of warning relatives about the condition versus the anxiety and guilt that may be triggered by this information.

Genetic counseling raises sensitive issues: Meeting with a genetic counselor and discussing risks of birth defects or disease can be a frightening prospect. Even collecting information about the family history can evoke memories of relatives who have died as well as other family secrets. The discussions can trigger a number of coping strategies from denial to overintellectualization. Within a counseling session, clients may exhibit a range of emotions, including grief, fear, anger, and even humor. Genetic counselors are well versed in counseling techniques that allow them to be empathetic and supportive throughout the interactions. Since emotional distress can derail the capacity to learn, counselors must also continually gauge the client's emotional state during the encounter and determine whether it is important to pause or explore these emotions further.

Genetics is complicated and can outpace treatments: Another challenge is the enormous amount of complex information that needs to be understood by the client. A discussion of risk will include information about biology, math, and statistics – concepts often not familiar to the average person. The discussion can have intense emotional overtones, since the information is about reproductive fitness or the health of the client and/or close relatives. The cloning of the 34 000 genes through the Human Genome Project provides great hope for future therapies and prevention of genetic disorders. However, currently, there are very few genetic conditions that can be fixed, cured, or prevented. Genetic testing has been described by clients as looking into a crystal ball to determine their fate, but at the moment, it remains a cloudy view. In most genetic conditions, uncertainties remain as to the severity of symptoms or, in the cases of adult-onset conditions, if and when the problems will occur.

7. Genetic testing is changing the landscape of medicine

In the 1970s, genetic counseling was about providing clinical service to prenatal and pediatric clients. The field has expanded into areas that did not exist 30 years ago, and much of the basic information about genetics is now being provided by primary care providers. The onset of predictive genetic tests will continue the shift in medicine from urgent care to prevention. The potential number of genetic predictive tests is staggering, in areas as diverse as disease prediction (e.g., heart-attack risk) and pharmacogenomics (e.g., targeting drugs to people's genotypes). Everyone likely has a genetic predisposition to one or more disorders. Therefore, the entire health care profession will need to be prepared to deal with a population of people at various genetic risks. This will require increased knowledge about genetics and greater access to genetic services, especially in underserved areas. Families will need to be reassured that genetic test results will not lead to discrimination from third-party sources, such as insurers, employers, or colleges. Finally, the increased availability of personalized genetic screens and subsequent additional medical care by at-risk people will potentially place a burden on medical services. Given the complexities of the human genome, genetic counselors and geneticists will continue to play important, albeit different roles, in the "genomic era".

Short Specialist Review

Ethical and legal issues in medical genetics

Mary Kay Pelias

GenELSI Consulting Inc., New Orleans, LA, USA

1. Introduction

Over the course of the twentieth century, the knowledge and technology of medical genetics expanded exponentially. From tenuous beginnings in descriptions of single-gene diseases, through the mid-century elucidation of the structure and functions of DNA, the practice of medical genetics has expanded to include a host of therapies, including specialized pharmaceuticals and the inception of gene transfer for controlling the ravages of deleterious genes. Concomitant with the growth of medical options, an array of ethical and legal questions has focused our attention on the interests and obligations of professionals, families, patients, and those who participate as subjects in medical research. Many of the ethical issues have received considerable debate and study. Some issues have generated resolution, while many continue to elude consensus among professionals in both clinical practice and scientific research arenas and among professionals and lay experts in bioethics.

2. Professional–patient and professional–subject relationships

Interactions between health care professionals and researchers, on the one hand, and their patients and subjects, on the other, evolved significantly over the twentieth century. The ancient Hippocratic admonition to "do no harm" acquired new meanings as the practice of medicine embraced such innovations as antisepsis and anesthesia. These advances and many others expanded the array of options that could be offered to patients and subjects, and these options resulted in significant shifts in the balance of relationships between health care providers and consumers. The physician–patient relationship traditionally followed the ethical principle of beneficence and was characterized by a fiduciary imbalance that is derived from the physician's specialized training and knowledge and the patient's relative lack of medical expertise. Indeed, the patient expected the knowledgeable physician to exercise his role of beneficence in making diagnostic and treatment decisions on behalf of the patient.

As medical knowledge and options continued to grow, the emphasis on professional beneficence shifted to an emphasis on the personal autonomy of patients and subjects, who became aware of multiple choices for decisions about health care. This new awareness was first articulated in civil litigation brought by plaintiff patients whose physicians had not acquired express permission for specific therapies or procedures. The foundation of respect for the patient's personal autonomy was articulated in a 1914 holding that "every human being of adult years and sound mind has a right to determine what shall be done with his own body" (*Schloendorff v. Society of New York Hospital*, 1914). This principle was applied in the world of biomedical research only after atrocities of human experimentation became public knowledge in the mid-twentieth century and the subject of protective legislation in the United States in the 1970s.

3. Informed consent

As the ethical principle of beneficence yielded to the ethical principle of personal autonomy, the courts and legislatures further defined the obligations of health care professionals in the principles of informed consent. These principles evolved along two pathways. In the civil litigation of medical negligence, health care professionals are now required to convey all "material" information to their patients, with "material information" defined as any information that could cause the patient to choose another option. In the legislative regulation of biomedical research, the research professional must provide the subject with information about the purpose and goals of the research, about possible risks and benefits of participation, and any alternatives, including the right to decline to participate and the right to withdraw without prejudice. Thus, the traditional fiduciary duty of professionals to make decisions for patients and subjects has yielded to a duty of the professional to inform the patient or subject fully so that he or she is equipped to make a rational choice among available options. This duty obligates the professional to be informed about new developments in medicine and research and to anticipate changes in the standard of care as the courts and legislatures become aware of new knowledge in basic science and new avenues of treatment (Pelias, 1991).

4. Genetic testing in children and parental autonomy

Exhaustive study during the 1990s of the risks and benefits of testing children for later-onset diseases resulted in guidelines for prudent decisions about generating genetic information on minors (ASHG/ACMG Report, 1995). Genetics professionals enjoy a consensus that the primary reason for testing children is to provide an immediate medical benefit. Beyond this justification, however, testing children for other reasons should be approached with caution. Such reasons might include, for example, plans for financial support, or trusts, for children, or plans to relocate near a center that specializes in medical care for particular disorders or diseases. Thorough and careful counseling should provide parents with information about both the risks and benefits of testing children and about how the information might

be disseminated to children judiciously, without causing psychological damage or creating negative stigmata. Once the genetics professional has provided such counseling, however, the professional should defer to the parents as the primary decision makers for their own families (Pelias and Markward, 2000).

5. Privacy and nondiscrimination

The concept of privacy in medicine and biomedical research can be viewed from three perspectives. Personal privacy describes privacy of the body and the sphere of personal space around the body that is shared only with consent. Decisional privacy describes personal autonomy in making decisions for oneself, as in the prescriptions for informed consent. Informational privacy describes the confidentiality of information that is shared in physician–patient and researcher–subject relationships.

While confidentiality is the cornerstone of the relationship of professionals to patients and subjects, a growing change is anticipated by arguments for a "duty to recontact" patients or subjects when significant new information becomes available. This issue has been litigated in at least three early medical malpractice cases not related to genetics, but these cases may eventually be resurrected for parallel arguments in the context of genetic testing. Further, the possibility of recontacting patients and subjects raises the question of establishing reciprocity in the professional relationship so that new information can be forwarded expediently to the benefit of both parties (Pelias, 1991). Similarly, genetics professionals are examining the possibility of a "duty to warn" at-risk relatives when genetic testing of a patient or subject indicates that relatives of the patient or subject might have an increased risk of bearing the same deleterious gene. Guidelines for discussing these exceptional circumstances with patients or subjects before testing and for respecting the rights of patients and relatives have been assembled in order to maximize medical benefits and reduce legal risks for both professionals as well as patients, subjects, and their relatives (Knoppers *et al*., 1998).

Confidentiality of genetic information has also become a focus of attention with respect to the insurance industry and protections in the workplace. Individuals whose private genotype information has been disclosed have lost health insurance coverage and, in some cases, have resorted to litigation to establish and protect their own interests. Some cases illustrate the poor understanding of insurance and workplace personnel in the science and implications of genetics (Billings *et al*., 1992). Indeed, egregious violations of personal privacy are documented in industrial settings when employers provide health care benefits and physical examinations that are stretched to include genotyping without the knowledge or consent of the employee. A significant outcome of the documentation of genetic discrimination and privacy violations is the plethora of state legislation efforts to prohibit such prejudicial and intrusive activities and to protect the privacy of the individual with respect to genes and genetic prospects (Roche, 2002). Finally, federal protections have been achieved under the Americans with Disabilities Act (ADA), in the Health Insurance Portability and Accountability Act (HIPAA), and in several recent congressional bills expressly aimed at protecting genetic privacy and preventing discrimination based on genotype (Hustead and Goldman, 2002).

6. Newborn screening and use of archived tissue samples

Genetic testing of newborn infants has conferred immense benefits to children and to the public for over four decades. Identification of some deleterious genotypes in the newborn period allows early initiation of treatments that prevent the accumulation of harmful metabolites that could otherwise cause retardation, serious illness, and even death. Because of the immense benefits that accrue from early detection and treatment, all but two states have legislated mandatory screening that circumvents the requirement of parental consent: the minor intrusion to obtain a few drops of blood is viewed as insignificant when weighed against the immense benefits of early detection and treatment.

New questions are arising, however, as the technology for testing expands to permit testing for genes that cause late-onset problems or are related to susceptibilities for complex disorders. The justification for mandatory screening for serious diseases of infancy and childhood may not be stretched to other genetic tests for which parental consent is appropriate, if not obligatory. Similar concerns arise over the recent thrust to obtain archived blood spots, with or without personal identifiers, for exploring new and future tests and technologies. Whether and how archived tissue samples may be used in future research remains an unsettled issue (Pelias and Markward, 2001).

7. Race, ethnicity, and pharmacogenetics

As the molecular structure of a growing number of genes is characterized, researchers in both academia and industry are focusing on designing pharmaceuticals that are tailored to interact with disease-related alleles or gene products. Such alleles are, however, often found to be concentrated in one or another racial or ethnic human group, unevenly distributed across the entire population. A major source of ethical concern derives from the possibility that smaller human groups will be characterized and stigmatized by their particular deleterious genes. Among suggestions for avoiding such negative social consequences of pharmacogenetics is a call for concentrated education programs directed to the general public. Such an effort is viewed as a massive undertaking but essential for public appreciation of human variance and the potential benefits of allele-specific pharmaceuticals (Rothstein and Epps, 2001).

8. Conclusions

The ethical and legal issues outlined above are past and present concerns in the practice of medical genetics, in genetic counseling, and in clinical and basic research. Some concerns, such as genetic testing in children and newborn screening for diseases of infancy, have attained satisfactory resolution. Others, however, such as newborn screening for late-onset diseases and susceptibilities and social questions in pharmacogenetics, remain unsettled. As yet, unanticipated ethical issues can be

expected to arise as we continue to explore the human genome and the nature of genetic health and disease. Perhaps, the most significant outcome of the discussions and studies of these issues is a new awareness among geneticists about ethical, legal, and social issues, and a new concern for fostering the understanding of these issues among the public at large and within smaller racial and ethnic groups in the human population.

Mechanisms of inheritance

Arthur S. Aylsworth
University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

1. Introduction

Gregor Mendel grew up in an area of central Europe called Moravia, where there was great interest in plant and animal breeding. As a young man, Mendel was intrigued by the observation that for some traits, when two individuals with different phenotypes are crossed, all members of the first generation express the trait characteristic of only one of the parents. The trait is faithfully expressed and is not a combination of the traits from the two parents. But when members of that first generation are crossed, the trait that had been lost suddenly reappears, perfectly expressed, in the next generation in a predictable and reproducible fashion. This "lost" trait is seen in one-quarter of the individuals produced, while the remaining three-quarters continue to express the trait seen in the previous generation. While studying in Vienna, Mendel formulated his hypothesis that heredity is determined by *units* that occur in pairs. He returned to his monastery at Bruno, and after spending 8 years carefully selecting seven traits in *pisum* that follow this pattern, proceeded to test and demonstrate the truth of his hypothesis. Note that it took Mendel many years to select a few traits that follow this inheritance pattern. That is because most traits in peas and humans do not obey these deterministic rules of expression that we now refer to as "Mendelian inheritance".

Mendel's great contribution was the discovery of *unitary inheritance*, which was in dramatic contrast to the then existing theory of *inheritance by a blending of characters*. Modern interpretations are usually summarized as the principles of *segregation* and *independent assortment*. The principle of segregation states that alleles are paired and each gamete normally receives only one member of each pair. Exceptions to this principle include trisomy and uniparental disomy. Independent assortment refers to the fact that pairs of genes tend to segregate independently of each other. The exception to this principle is genetic linkage.

The concepts of *dominant* and *recessive* defined by Mendel refer to the *phenotypic expression* of alleles in heterozygotes, not to intrinsic characteristics of gene loci. Therefore, the older practice used by some early geneticists of referring to a locus as dominant or recessive should be avoided.

In diploid organisms, a *homozygote* (adj. *homozygous*), strictly speaking, is an individual that has two identical alleles at a gene locus, while a *heterozygote* (adj. *heterozygous*) has two different DNA sequences at a particular locus. Note that in

the fields of human and medical genetics, the term "homozygote" is also frequently used to refer to an individual with a homozygous phenotype, even though the genotype may consist of two different disease-causing mutations. Such individuals are *compound heterozygotes* or *allelic compounds*.

Inheritance patterns are determined by one or more genes. From a functional standpoint, genetic factors can be thought of as monogenic or multigenic and deterministic or nondeterministic. Medical geneticists traditionally subdivide inheritance patterns into (1) chromosome abnormalities (multigenic, deterministic), (2) single-gene disorders (monogenic and usually deterministic, but sometimes nondeterministic), and (3) multifactorial or complex conditions (multigenic, nondeterministic). One also must consider the roles of environment, epistasis, and chance in the production of phenotypic expression.

Exceptions and variations on the simple, basic themes of monogenic inheritance commonly involve issues of *penetrance* and *expression*.

1.1. Penetrance

Penetrance (P) refers to the proportion of gene carriers that express a particular trait. P ranges from 0 to 1 (or 0 to 100%). Traits or conditions with decreased or incomplete penetrance ($P < 1.0$ or $< 100\%$), therefore, fall into the category of monogenic nondeterministic inheritance.

1.2. Expression

Expression refers to the observable characteristics of the phenotypic trait in question such as quantity, quality, severity, age of onset, body part or organ system involved, and so on. Variable expression may occur within families (intrafamilial variability) or between/among different families (interfamilial variability). Intrafamilial variability may be due to epistasis, environment, chance, or mosaicism. Interfamilial variability may be due to epistasis, environment, chance, and allelic or locus heterogeneity.

Penetrance and expression may be affected by the gender of an individual, the age of an individual (i.e., time), transmission through families, environmental factors, the effects of other genes (epistasis), stochastic factors (chance), and the presence of mosaicism.

- Examples of sex-influenced expression include male pattern baldness, breast and ovarian cancer, and anomalies of internal and external genitalia.
- For all disorders of postnatal onset, penetrance will depend on age. It should be noted that the term "variable penetrance" is commonly misused for the concept of "variable expressivity". In fact, the term "variable penetrance" is only appropriate for conditions of postnatal onset, where there are different penetrance figures at different ages.
- Transmission through a family can be associated with a change in the size and, therefore, the deleterious effects of trinucleotide repeat expansion mutations, a process called *anticipation*. *Imprinting* causes expression to be determined by

the gender of the transmitting parent (*see* Article 36, **Variable expressivity and epigenetics**, Volume 1).

- Environmental factors may be required for phenotypic expression. For example, the autosomal recessive inborn error of metabolism phenylketonuria is characterized by mental retardation. But a genetic deficiency in the activity of the enzyme phenylalanine hydroxylase requires dietary phenylalanine to produce this deleterious phenotype.
- Epistasis is assumed to be a ubiquitous principle, based on developing knowledge about the complexities of genetically determined biomolecular interactions in cells and tissues and on data collected from plant and animal experiments. For most or all traits, expression of an allele probably depends at some level on interactions with other gene products.
- A factor traditionally ignored in discussions about the cause of genetic disease is chance. Kurnit *et al*. (1987) used computer modeling to show that some of the non-Mendelian familial clustering of anomalies usually attributed to concepts such as "reduced penetrance" and "multifactorial inheritance" may be accounted for by simple, random chance. Central to this concept is the idea that biological processes, like many other phenomena that we encounter daily, are error-prone, nonlinear systems. The complex processes of embryologic development and physiologic homeostasis may be very sensitive to small perturbations, which are by themselves "within normal limits", that subsequently, *by chance*, are amplified by the randomness that is inherent in all such systems.
- Mosaicism describes the situation in which an individual has cells with more than one genotype. For example, females are mosaic for X-linked gene expression, because some of their cells express the father's X and other cells express the mother's X. Individuals with sporadic (i.e., nonfamilial) cases of autosomal dominant disorders may have less severe manifestations than those who inherit the condition from a parent because in some sporadic cases, the mutation occurred in the postfertilization zygote and only a fraction of body cells carry the mutant allele. Postzygotic chromosome rearrangements cause a mosaic pattern to be found on karyotyping (*see* Article 18, **Mosaicism**, Volume 1). Postzygotically acquired mutations may be evenly distributed throughout the body (e.g., mild osteogenesis imperfecta caused by mosaicism for a severe lethal disease mutation), limited to specific parts or sides of the body (e.g., segmental neurofibromatosis type I), or limited to specific tissues of origin (e.g., tissue-specific mutations and chromosome rearrangements associated with malignancy).

2. Multigenic deterministic inheritance

This category includes abnormalities that involve large segments of the genome, traditionally called "chromosome abnormalities" in standard texts (*see* Article 11, **Human cytogenetics and human chromosome abnormalities**, Volume 1, Article 12, **The visualization of chromosomes**, Volume 1, Article 13, **Meiosis and meiotic errors**, Volume 1, Article 16, **Nondisjunction**, Volume 1, Article 17, **Microdeletions**, Volume 1, Article 22, **FISH**, Volume 1, Article 67, **Approach to**

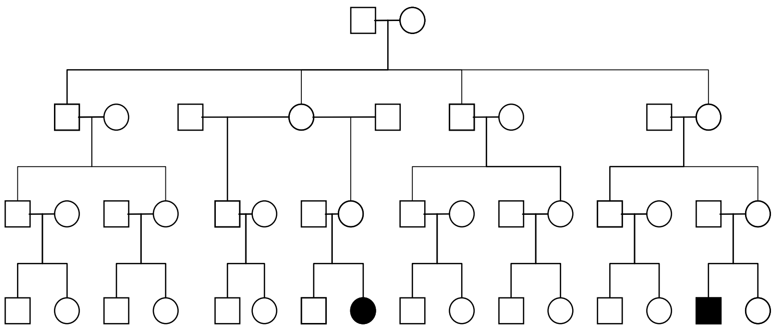

Figure 1 Pedigree with only two second cousins affected out of 30 relatives in a four-generation family. Such pedigrees are frequently assumed to be explained by complex or multifactorial inheritance. Note that this pedigree is also consistent with several other possible mechanisms of inheritance including the following: an unbalanced chromosomal rearrangement where intervening, unaffected relatives carry the balanced rearrangement; autosomal dominant with incomplete penetrance; X-linked inheritance with incomplete penetrance in heterozygous females; and mitochondrial inheritance where expression depends on an environmental exposure such as aminoglycoside-induced deafness (compare with Figure 2)

rare monogenic and chromosomal disorders, Volume 2, Article 71, **Advances in cytogenetic diagnosis**, Volume 2, and Article 87, **The microdeletion syndromes**, Volume 2). Examples include trisomies, partial trisomies, partial monosomies, and smaller duplications and deletions. Cytogenetically detectable abnormalities are found in a little over 0.5% of newborn babies, and in a much higher percentage of miscarriages and fetal deaths. Submicroscopic cytogenetic rearrangements include microduplications and microdeletions that cause "contiguous gene" syndromes.

Submicroscopic microdeletions and microduplications may be vertically transmitted from generation to generation as are the autosomal dominant disorders described below. Syndromes caused by chromosome abnormalities may be inherited through families in a pattern suggesting complex or multifactorial inheritance (Figure 1). For example, cousins may have unbalanced karyotypes and be affected, while intervening, phenotypically unaffected relatives are asymptomatic carriers of a balanced chromosomal rearrangement.

3. Monogenic deterministic inheritance

Frequently called "Mendelian" inheritance patterns, these are well covered in standard textbooks of genetics. They include the "single-gene disorders", autosomal and X-linked dominant and recessive inheritance, and mitochondrial patterns. The major features are summarized below.

3.1. *Autosomal dominant inheritance*

This occurs when one allele of a heterozygous pair causes a phenotypic trait. Many classic human genetic disorders are caused by this mechanism and follow this pattern. An organism heterozygous for the trait-causing allele has a 50% chance,

or one chance out of two, of passing that allele on to each offspring. Transmission in families, therefore, is from one generation to the next in a pattern that is sometimes called "vertical inheritance". Males and females are typically both affected and affected equally unless there is sex-limited expression. Male-to-male transmission occurs, distinguishing this from X-linked dominant inheritance.

Mendel's definition of dominant expression was that the heterozygote appeared identical to the mutant homozygote. In human genetics, autosomal dominant diseases are relatively rare (frequencies generally less than one in several thousand). Therefore, heterozygote matings are extremely rare, and the human homozygous phenotype is unknown for most human "dominant" disorders. A few are known. Huntington disease appears to be a true Mendelian dominant because homozygote and heterozygote expressions are similar. On the other hand, the condition known as classic achondroplasia, traditionally called an autosomal dominant, is not. Homozygous offspring from two heterozygous parents are typically much more severely affected, and usually die at birth or in the first few weeks of life. Heterozygous achondroplasia is compatible with long survival and reproduction, while homozygous achondroplasia is a genetic lethal. Other terms used to describe this phenomenon include "incomplete dominant" and "semidominant" inheritance.

A paternal age effect is observed for some autosomal dominant traits. This refers to the phenomenon where new mutations are associated with advanced paternal age because mutations due to unrepaired DNA copy errors increase proportionally with increasing paternal age.

3.2. Autosomal recessive inheritance

This occurs when two phenotypically normal parents carry mutant alleles at the same locus and produce a phenotypically affected offspring that inherits a mutant allele from both parents. Penetrance in heterozygotes is zero, because they appear identical to the wild-type homozygotes. Because affected sibs may be produced by heterozygous parents, this pedigree pattern has been referred to as "horizontal inheritance". Carrier parents have a 25% risk, or one chance out of four with each pregnancy, of having a child who is affected by virtue of being homozygous or an allelic compound. Unaffected sibs of affected patients each have a two-third chance of being a carrier.

Consanguinity is frequently a cause of both parents carrying the same rare recessive allele. Parental consanguinity is not significantly increased, however, for common recessives such as sickle-cell disease, cystic fibrosis, or hemochromatosis. Consanguinity can result in a phenomenon called "pseudodominant inheritance". This occurs when a homozygous (or compound heterozygous) affected individual mates with an unaffected heterozygote, producing an affected offspring. A parent and child are affected but the condition is autosomal recessive because the heterozygote is not affected. Pseudodominant inheritance of common recessive traits does not require consanguinity.

3.3. X-linked inheritance

This occurs when a phenotype is caused by an allele on the X chromosome. Because of the pedigree patterns produced, this type of inheritance is sometimes called

"diagonal inheritance". X-linked inheritance is characterized by the lack of male-to-male transmission and the fact that affected males pass their mutation-bearing X chromosomes on to all of their daughters but to none of their sons. Traditionally, human geneticists talk about X-linked recessive and dominant disorders. The former is characterized by no apparent manifestations in carrier females, but sometimes, subtle findings are apparent if a careful evaluation is performed. The latter term is used when both males and females are significantly affected, even though on close examination differences may be found.

3.4. Autosomal and X-linked intermediate expression

When carrier females have a phenotype much milder than that of affected males, a term such as X-linked intermediate may be used. In fact, because of random variation in Lyonization, a variable degree of phenotypic expression can be expected in females who carry alleles for X-linked disorders and traits.

Phenotypes may be dominant or recessive depending on how one defines them. For example, the disease sickle-cell anemia is autosomal recessive but the phenomenon of in vitro sickling is a dominant trait.

Some genes may produce a wide range of mutant phenotypes. Mutations at the locus for the tissue nonspecific alkaline phosphatase gene may be recessively expressed (i.e., no phenotype in the heterozygote but severe hypophosphatasia in the homozygote or allelic compound) or dominantly expressed as childhood or adult-onset hypophosphatasia. Heterozygous carriers of alleles that cause the recessive, multisystem disorder homocystinuria may have a degree of hyperhomocyst(e)inemia that places them at increased risk for adult vascular disease. It seems reasonable to predict that future research may find subtle phenotypic effects associated with heterozygosity for a number of other recessive disorders.

3.5. Y-linked inheritance

Holandric inheritance occurs when a phenotype is caused by an allele on the Y chromosome and is characterized by exclusive and obligatory male-to-male transmission. As of November 2004, the OMIM database (OMIM, 2000) listed 45 genes or phenotypes in the Y-linked catalog.

3.6. Mitochondrial inheritance

When a phenotype is caused by an allele in the mitochondrial genome, a pedigree phenomenon called "maternal inheritance" is produced, whereby all of the offspring of an affected woman are either affected or nonpenetrant carriers and none of the offspring of affected men are affected or carriers (Figure 2). Variable expression is due to the fact that within an organism's cells there is a mixture of normal and mutant mitochondria (heteroplasmy). Lower levels of mutant mtDNA are associated with milder or minimal symptoms, while higher levels cause more severe disease expression.

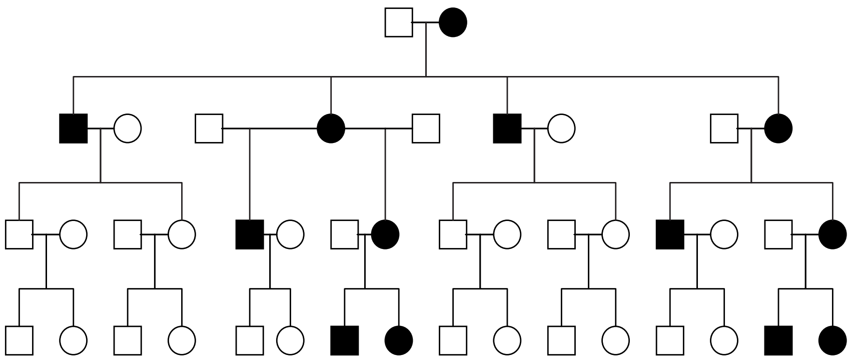

Figure 2 Pedigree showing maternal inheritance of a trait caused by a mutation in mitochondrial DNA. All offspring of affected women are also affected, while none of the offspring of affected males are affected

4. Monogenic nondeterministic inheritance

This category is frequently covered in standard texts as exceptions to Mendelian inheritance. When lifetime penetrance is incomplete, some individuals who carry disease-causing genes will be unaffected. Conditions with lifetime penetrance figures that range from 99% down to 10% or so usually are recognized and classified as monogenic disorders with incomplete penetrance. That is, they are recognized as having a major single genetic factor that causes the disorder. On the other hand, it is not clear how to classify conditions or traits caused by a single major genetic factors with penetrances of 1, 5, or even 10%. These can be thought of as *susceptibility genes* that predispose an organism to develop a particular trait or disease. Figure 1 shows a pedigree of a family segregating such a low penetrance, disease-susceptibility gene.

The less deterministic a single major gene effect, the more likely interactions with other gene products and environmental factors will significantly affect expression. Acute intermittent porphyria is an autosomal dominant condition with incomplete penetrance that depends on environmental exposures. Similarly, hemochromatosis is an autosomal recessive susceptibility genotype with low penetrance that interacts with environmental factors to produce disease. A classic example of an autosomal dominant structural anomaly with incomplete penetrance is split-hand split-foot malformation. In this case, there is some experimental evidence that phenotypic expression is affected by other genes (i.e., the individual's genetic background). Since the factors that influence penetrance and expressivity may be a mix of genes and environmental factors, the monogenic model, in practice, may actually be a complex "mixed" model of major single-gene effects on a polygenic background, where liability may be determined by more than one gene.

Many instances of mitochondrial inheritance fit in this category also. Variable expression and even incomplete penetrance may be due to heteroplasmy. Figure 1 illustrates how mitochondrial inheritance, using the same pedigree transmission as in Figure 2, can suggest complex or multifactorial inheritance. In this case,

the mitochondrial mutation required an environmental exposure for phenotypic expression. An example of this would be aminoglycoside-induced deafness.

5. Multigenic nondeterministic inheritance

The terms "complex inheritance" or "complex disease" imply that a single, causative, completely penetrant gene does not always produce the phenotype in question (*see* Article 57, **Genetics of complex diseases: lessons from type 2 diabetes**, Volume 2, Article 58, **Concept of complex trait genetics**, Volume 2, and Article 59, **The common disease common variant concept**, Volume 2). Instead, a combination of effects from more than one gene, or one or more genes with environmental (nongenetic) factors may produce the phenotype. "Complex" phenotypes are *causally heterogeneous*. This usually means that over an extended population, the causes of a particular phenotype, trait, or disease may include both low frequency, high-penetrance causative (i.e., deterministic) alleles and more common, low-penetrance susceptibility alleles interacting with environmental factors. Most of the common disorders of children and adults are complex phenotypes. The common disorders of childhood include birth defects, mental retardation, and short stature. Common disorders in adults include cancer, diabetes, cardiovascular disease, hypertension, stroke, the psychoses, and so on. These conditions are frequently familial, but pedigrees usually do not suggest a straightforward pattern of Mendelian inheritance (Figure 1)

To explain these "non-Mendelian" patterns of familial recurrence, mathematical models were developed that assumed a continuous distribution of genetic "liability" to malformation or disease in the general population. "Polygenic" determination initially referred to a mathematical model in which a number of genes with small, additive effects provide an underlying genetic predisposition to malformation or disease. Some quantitative traits and clinical disorders in humans have been studied and found to be compatible with this mechanism of determination. "Multifactorial" describes models in which environmental factors interact with genetic predisposition, which is frequently thought of as polygenic. In the case of quantitative traits such as blood pressure, weight, and height, a normal curve would represent the distribution of measurements in a population. This model was adapted to account for discontinuous traits by the addition of a threshold, the point within that liability distribution beyond which individuals are affected.

5.1. Digenic causation

This designates a subset in which diseases or traits result from mutations in two genes at different loci. For example, if two unlinked genes encode polypeptide subunits of a functional protein complex, then mutations in either or both genes cause dysfunction and clinical phenotypes. While this may seem like a simple variation on the theme of monogenic inheritance, it is included under "multigenic nondeterministic inheritance" because its existence confounds standard linkage analysis. Examples include some forms of retinitis pigmentosa, nonsyndromic

hearing loss, junctional epidermolysis bullosa, and autosomal dominant polycystic kidney disease.

5.2. Oligogenic causation

"Oligogenic" designates a subset of "polygenic" causation in which diseases or traits result from the effects of relatively few genes, some of which may have rather large effects. Many current research efforts are directed toward identifying a small number of interacting genes that produce clinical phenotypes and diseases, without the necessity of identifying a quantitative, polygenic background of susceptibility. An example is Hirschsprung disease (HSCR), a disorder characterized by congenital absence of ganglion cells in the wall of the colon. Eight incompletely penetrant genes from three different but interacting signaling pathways are implicated in causing HSCR.

5.3. Environmental factors

These influence both embryonic development and adult disease. For example, the risk of developing emphysema is greater in individuals with both an environmental exposure such as smoking and a genetic predisposition such as alpha-1-antitrypsin deficiency than it is for individuals with only one of these risk factors or none at all. Severe respiratory distress in asthmatics is triggered by exposure to environmental triggers. Those with a familial susceptibility to skin cancer can decrease their risk of developing cancer by modifying their sun exposure. Obesity strongly affects morbidity in individuals with inherited susceptibilities to type II diabetes.

The relative merits of hypothetical models such as polygenic, multifactorial threshold, and major single gene with incomplete penetrance have been debated vigorously over the years. It seems reasonable to assume that complex phenotypes result from many different stochastic combinations of genetic and environmental factors, where the genetic contribution may be from one or more genes, and expression is merely a possibility, pending environmental exposure(s) and/or random fluctuations of normal processes in the embryo, fetus, or adult organism.

Genetic family history, pedigree analysis, and risk assessment

Robin L. Bennett
Division of Medical Genetics, University of Washington, Seattle, WA, USA

1. Introduction

An array of high-tech genetic diagnostic tools have ushered in the era of genomic medicine (*see* Article 71, **Advances in cytogenetic diagnosis**, Volume 2 and Article 72, **Current approaches to molecular diagnosis**, Volume 2). Yet, obtaining a medical family history remains one of the most powerful but simple and cost-effective approaches to identifying individuals at risk for rare single-gene disorders as well as for common disorders with a genetic etiology (e.g., cancer, dementia, heart disease, stroke, diabetes, etc.). Health care professionals and genetic researchers should have basic competence in obtaining and interpreting a family medical history and pedigree (refer to NCHPEG genetics core competencies at **www.nchpeg.org**). A pedigree is an important method of establishing patient rapport, and serves as a visual demonstration for providing patient education (e.g., on variation in disease expression in a family), as well as identifying other relatives at risk for disease or who can be informative for inclusion in genetic research (Bennett, 1999).

2. Obtaining a pedigree

Typically a pedigree includes two generations of ascent from the consultand (the person requesting the medical or genetic information) or proband (the affected individual that brings the family to medical attention), and two generations of descent. Information is usually collected on first-degree relatives (children, siblings, and parents), second-degree relatives (half-siblings, aunts, uncles, nieces, nephews, grandparents, and grandchildren), and sometimes third-degree relatives (e.g., first cousins). For example, pedigree assessment for a 60-year-old man with a family history of colorectal cancer would include information about his parents, grandparents, aunts and uncles, and possibly his cousins. If a condition is suspected of being inherited, the pedigree is extended back as many generations as possible to include affected relatives.

Standardized pedigree symbols (Figures 1, 2, and 3) are used to record relationships and medical information in the form of a pedigree (Bennett *et al*., 1995). The square or circle representing an affected relative can be shaded. More than one condition can be shown on the pedigree by partitioning the circle or square into two or

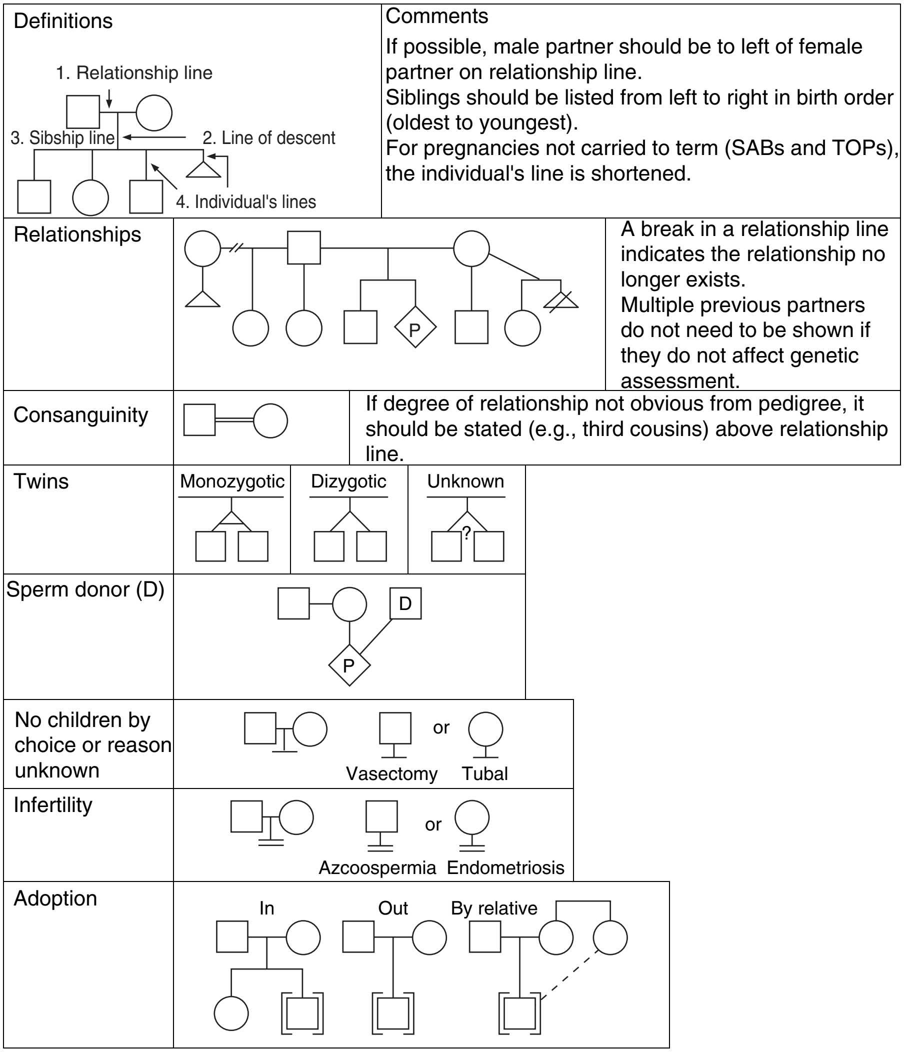

Figure 1 Common pedigree symbols (Reproduced from Bennett *et al*., 1995 by permission of University of Chicago Press)

four sectors and shading the appropriate sector or using different fill patterns (e.g., hatched). A pedigree key or legend is used to identify the medical conditions that are being traced in the pedigree and to explain any unusual abbreviations or less commonly used symbols (e.g., a gamete donor, adoption). Record on the pedigree: the age of relatives, their age at diagnosis of the condition in question, their age at death, and the cause of death. It is important to include both affected and unaffected relatives on the pedigree. The date the pedigree was obtained should be noted (for easy reference) as well as the name of the person who obtained the information.

Ideally, corroboration of the clinical diagnosis with medical records or death certificates provides the most accurate information for pedigree analysis and risk

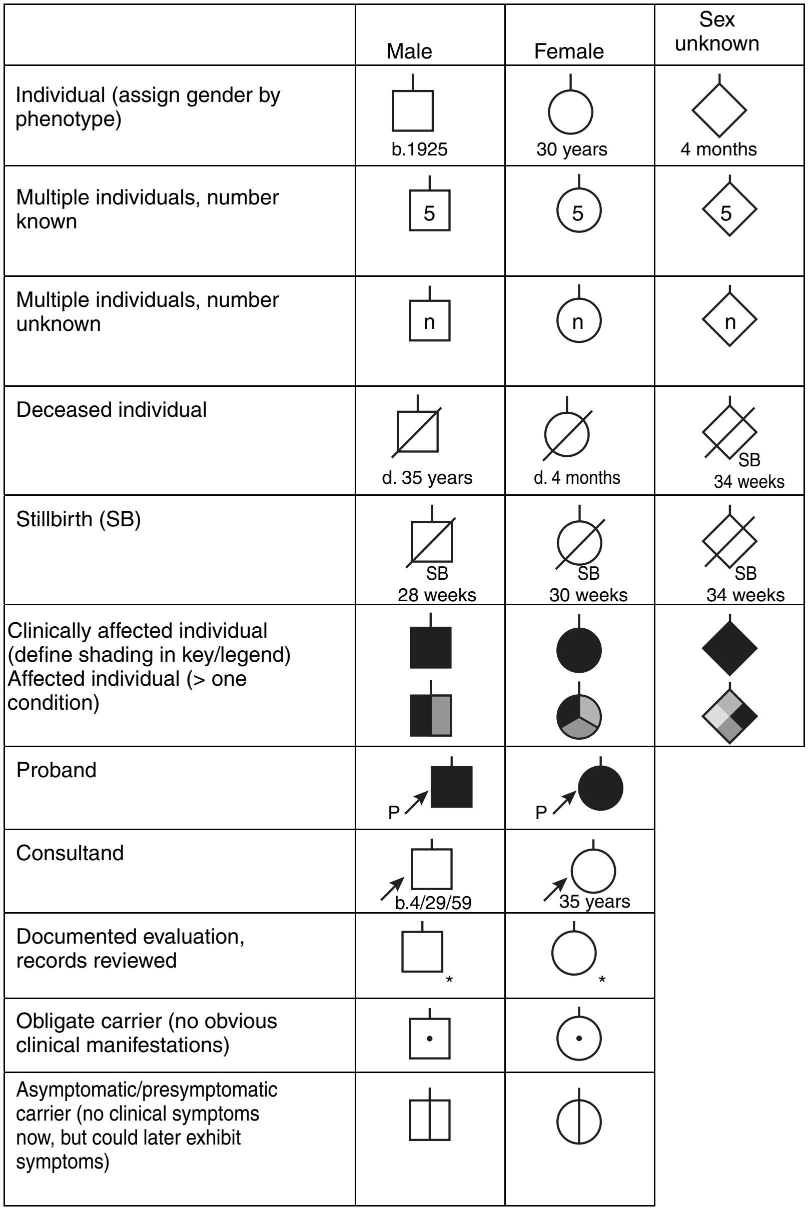

Figure 2 Standardized nomenclature for relationships in human pedigrees (Reproduced from Bennett *et al*., 1995 by permission of University of Chicago Press)

assessment. Even family photographs may be helpful when attempting to confirm a diagnosis. A client's recall of information about second- and third-degree relatives (e.g., aunts and uncles, grandparents, and cousins) is much less likely to be accurate than the information about more closely related relatives (e.g., siblings, parents, and children) (Bennett, 1999).

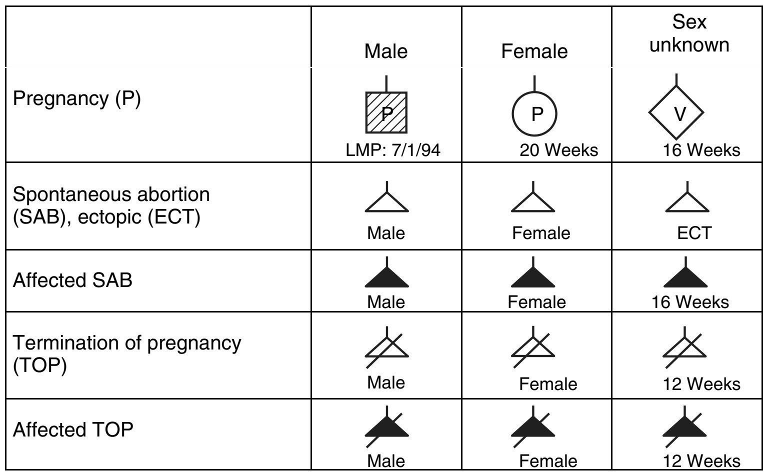

Figure 3 Standardized pedigree symbols and nomenclature for pregnancies and pregnancies not carried to term (Reproduced from Bennett *et al.*, 1995 by permission of University of Chicago Press)

The concept of race and ethnicity in genetic terms is evolving, but it is useful to note the countries of ancestral origin on a pedigree because the genetic risk assessment and the approach to genetic testing may vary on the basis of the client's ethnicity. For example, the likelihood of finding a BRCA1 or BRCA2 mutation in an individual with a family history of breast cancer who is of Ashkenazi ancestry is higher than for a person with a similar history of breast cancer who is Caucasian (Frank *et al.*, 2002; **www.myriadtests.com/provider/doc/mutprev.pdf**). Document the ancestral origins of both sets of grandparents (e.g., German, Japanese, Italian, Amish). Noting consanguinity (relationships between individuals with a common ancestor) is important for genetic risk assessment. Individuals with a common ancestor are more likely to share the same deleterious genes in common.

3. Pedigree tools

The pencil-and-paper approach to taking a family history remains a cheap and simple way of collecting family history. There are several software programs for use by professionals to record family histories that are particularly useful for large families involved in research protocols. Several on-line resources that can be downloaded to a personal computer have been developed to encourage clients to collect, organize, and maintain their medical family history, which can then be made available to their health care professionals (Guttmacher *et al.*, 2004). These include pedigree tools developed through the National Human Genome Resource Institute and the Centers for Disease Control (**www.hhs.gov/familyhistory**), the American Medical Association (**www.ama-ass.org/ama/pub/article/2380-2844.html**), and a joint collaboration of the National Society of Genetics Counselors, the Genetic Alliance, and the American Society of Human Genetics (**www.nsgc.org**), and the March of Dimes (**www.marchofdimes.com**).

4. Pedigree analysis and risk assessment

One of the major purposes of drawing a pedigree is to recognize patterns of inheritance. Table 1 reviews the basic patterns of inheritance and variables that can mask the recognition of these patterns.

Statistical risk assessment based on pedigree analysis, epidemiology (such as Hardy–Weinberg equilibrium), various risk models (such as Bayes theorem), and the sensitivity and specificity of various genetic tests is central to genetic counseling and risk assessment (Claus *et al*., 1994; Gail *et al*., 1989; Nussbaum *et al*., 2001; Parmigiani *et al*., 1998, Young, 1999). Genetic counseling involves explaining risks in multiple ways, such as distinguishing absolute from relative risks (e.g., a 10% absolute risk but a threefold increased risk), and using percentages to frame the magnitude of risks from different perspectives. For example, if autosomal recessive is the mode of inheritance, the chance of having an affected child would be framed in terms of a 25% or one in four chances of occurrence or recurrence, as well as a 75% chance of or three in four chances that a son or daughter would be unaffected. Comparing individual risk to population risks can help clients put their personal risk in perspective. Clinicians and researchers should attempt to remove their own biases about whether a risk is high or low from presentation of risk information.

A client's and family's reaction to genetic risk will depend on multiple variables including what are the client's preconceived notions about patterns of inheritance, chances of testing positive, or developing the family disorder? If the genetic risk information is divergent from a client's perception, the client may have difficulty incorporating the information or implementing any disease-management recommendations. What are the personal, family, religious, and cultural beliefs about disease causation? Reactions will also depend on the perceived burden of the condition – does the person have personal experience with the condition, and if so, have relatives survived the disease or has the disease been debilitating and/or resulted in early death? Other factors that are relevant to risk perception include level of cognitive functioning, temperament, and personality (e.g., pessimists or optimists, high-achievers who plan to "beat the risk"), external or internal locus of control, and coping style (e.g., information seekers, avoidance, dependency) (Bottoroff *et al*., 1998; Hallowell *et al*., 1997; McCarthy Veach *et al*., 2003).

5. Summary

A pedigree is an important instrument for genetic diagnosis and research. A pedigree can be used to establish the pattern of inheritance and diagnosis of a condition, and to demonstrate familial variation in disease expression (e.g., variable age of onset, variable disease severity). A pedigree can help a practitioner decide upon molecular testing strategies. It is also an excellent way to establish patient rapport and provide patient education. A pedigree can be recorded through a simple and easily available pen-and-paper method or incorporated into software tools that provide an easy mechanism to update the pedigree with new family history information, and to incorporate data analysis tools to help in the interpretation of

Table 1 Examples of clues for recognizing patterns of inheritance and variables that can mask the recognition of these patterns

Inheritance pattern	Mode of transmission	Pedigree clues	Confounding factors	Disease examples
Autosomal dominant	50% risk to each son/daughter	Condition in consecutive generations Male–male transmission Males/females affected Often variability in disease severity Homozygotes may be affected more severely Homozygous state may be lethal	Reduced penetrance Can miss diagnosis in relatives if there is a mild expression for disease New mutations may be mistaken for sporadic if family size is small	Neurofibromatosis 1 Breast–ovarian cancer syndrome Postaxial polydactyly Familial adenomatous polyposis Marfan syndrome Myotonic muscular dystrophy
Autosomal recessive	25% risk to each son/daughter Parents "healthy"	Usually one generation Males/females affected Often seen in newborn, infancy, childhood Often inborn errors of metabolism May be more common in certain ethnic groups (e.g., Tay–Sachs disease and Ashekenazism) Sometimes parental consanguinity	May be mistaken as sporadic if family size is small If carrier frequency is high, can look autosomal dominant (e.g., hemochromatosis)	Hemochromatosis Cystic fibrosis Sickle-cell anemia Phenylketonuria Tay–Sachs disease Beta-thalassemia Nonsyndromic neurosensory deafness Medium-chain-acyl-dehydrogenase deficiency (MCAD)
X-linked dominant	Heterozygous women affected with 50:50 risk to have affected daughter/50:50 chance for affected male (though lethal)	Females usually express condition but have milder symptoms than males No male-to-male transmission Often lethal in males so paucity of males in pedigree is seen	Small family size	Incontinentia pigmenti Orofacial digital syndrome 1 Rett syndrome

		May see multiple miscarriages (due to male fetal lethality) Females usually express condition but have milder symptoms than males		
X-linked	Women have 50% chance for affected son/50% chance for heterozygous daughter	No male-to-male transmission Males affected Females may be affected, but may be milder and/or with later onset than males	May be missed if paucity of females in family Lyonization	Duchenne muscular dystrophy Red-green color blindness Hemophilia A Fabry disease Fragile X syndrome
Chromosomal	Increased risk for trisomy observed with advanced maternal age Risk for affected fetus depends on specific chromosomal rearrangement (ranges from 1 to 15% or higher)	Suspect if the individual has 2+ major birth defects or 3+ minor birth defects Fetus with structural anomalies Unexplained MR (static) especially with dysmorphic features Unexplained psychomotor retardation Ambiguous genitalia Lymphedema or cystic hygroma in newborn Couples with three or more pregnancy losses Individuals with multiple congenital anomalies and family history of MRUnexplained infertility		Trisomy 21 (Down syndrome) Trisomy 18 Turner syndrome (45,X) Robertsonian translocations Reciprocal translocations Subtelomeric defects

(*continued overleaf*)

Table 1 (*continued*)

Inheritance pattern	Mode of transmission	Pedigree clues	Confounding factors	Disease examples
Mitochondrial	0–100%	No male transmission to offspring, only maternal transmission	Generally considered rare	Mitochondrial encephalopathy with ragged-red fibers (MERRF)
		Highly variable clinical expression		Mitochondrial encephalopathy, lactic acidosis, strokes (MELAS)
		Often central nervous disorders		Neropathy with ataxia and retinitis pigmentosa (NARP)
		Males and females affected, often in multiple generations		Neural tube defects
Multifactorial	Based on empiric risk tables	Males and females affected	May actually be single gene (e.g., missing diagnosis of velocardiofacial syndrome in family with cleft palate and congenital heart defect)	Neural tube defects
		No clear pattern		Scoliosis
		Skips generations		Cleft lip
		Few affected family members		Schizophrenia
				Bipolar disorder

MR = mental retardation. (Adapted from *Primary Care Clinics in Office Practice*, V1: 495–497, Acheson LS *et al*., The family medical history, Copyright 2004, with permission from Elsevier)

pedigree information. Its usefulness will continue to develop in tandem with the growing spectrum of molecular, bioinformatics, and proteomic tools.

The physical examination in clinical genetics

Marni J. Falk
Case Western Reserve University School of Medicine, University Hospitals of Cleveland, Cleveland, OH, USA

Nathaniel H. Robin
University of Alabama at Birmingham, Birmingham, AL, USA

1. Introduction

The physical examination is a valuable tool in medical practice that provides an objective supplement to historical information (*see* Article 78, **Genetic family history, pedigree analysis, and risk assessment**, Volume 2). To understand the special nature of the "genetic" physical exam, one must first recognize that the primary goal of a medical genetic evaluation is to identify a unifying etiology for seemingly unrelated birth defects, developmental problems, or other abnormal findings present in a fetus, child, or adult. Some may question the benefits of making a genetic diagnosis, as there are very few "cures" for such conditions. However, it is only by establishing a correct diagnosis that appropriate clinical management can be provided, along with accurate prognostic and recurrence risk counseling (*see* Article 75, **Changing paradigms of genetic counseling**, Volume 2). Understanding the pathogenesis of a patient's problems can further help families begin to cope with guilt they may feel about "why" their child has a particular problem and can direct families to contact appropriate support groups.

The genetic physical exam relies heavily on the art of dysmorphology, defined as the study of abnormal form (Aase, 1990). A detailed analysis of body structure is employed to detect potential embryologic deviations from normal development. While the actual physical examination is similar to the general medical examination, much closer attention is given to form, size, proportion, positioning, spacing, and symmetry (Hall, 1993). Indeed, precise observation and accurate description of all physical features is the cornerstone of the genetic dysmorphology exam. A genetic diagnosis may subsequently be reached through careful collation, interpretation, and categorization of any physical differences present (Hall, 1993; *see also* Article 74, **Molecular dysmorphology**, Volume 2).

2. Categorization of physical abnormalities

Physical exam findings that are indicative of a genetic diagnosis may be of varying clinical relevance. *Major anomalies* are structural alterations arising during embryologic development that have severe medical or cosmetic consequences and typically require therapeutic intervention. Examples include congenital heart defects, neural tube defects, and cleft lip or palate. *Minor anomalies*, in contrast, are medically and cosmetically insignificant departures from normal development that do not require significant surgical or medical treatment and have no risk for long-term sequelae. Minor external anomalies most commonly are found in areas where structures are most complex and variable, such as in the face, auricles, hands, and feet. Examples include wide-set eyes, low-set ears, or brachydactyly (short fingers or toes). A third category of physical findings is *minor*, or *normal*, *variants*. While these findings may also represent medically insignificant departures from normal development, they occur at a low frequency among the normal general population. Examples include café-au-lait macules, single palmar creases, and fifth finger clinodactyly. It is important to appreciate that minor anomalies and variants are significant only when taken in context. For example, while preauricular ear pits are common in the general population, they may lead to the diagnosis of branchio-oto-renal syndrome when identified in a patient with sensorineural hearing loss and renal anomalies.

Although major anomalies are more obvious and tend to draw attention to the patient more quickly, it is important to recognize that they are not more important than minor anomalies or normal variants as clues to a diagnosis (Hall, 1993). Rather, it is often the most subtle findings, discernable only through a genetics physical exam, that lead to the diagnosis of a genetic syndrome. Learning to differentiate a minor anomaly from normal variation is vitally important, as it is through these subtle anomalies that most genetic diagnoses are made. In particular, the rarer physical features may be the most useful in arriving at the correct differential diagnosis. Descriptions of normal features and variations can be found in excellent texts such as Diagnostic Dysmorphology (Aase, 1990) or Smith's Recognizable Patterns of Human Malformation (Jones, 1997).

3. Guidelines to performing the genetic physical exam

The exam itself has two interrelated components: descriptive observation and careful measurement. Each physical feature should be evaluated, then normal and variant features should be accurately described using accepted standard terminology. While impressions are important (e.g., "the palpebral fissures look small"), they are insufficient alone. "No clinical judgment should ever be made on a measurable parameter without actually having measured and compared it to standard references" (Hall, 1993). For example, hypertelorism (widely spaced eyes) noted on casual observation may be an illusion caused by a widened nasal bridge or epicanthal folds; measuring interpupillary distance may reveal that eye spacing actually falls within the normal range. Distinguishing such differences may be of considerable importance when trying to determine if minor anomalies are present and consistent with a particular syndrome.

In some instances, a genetic syndrome can be diagnosed by the overall appearance, or "gestalt" of the facial appearance. This ability to instantaneously recognize a syndrome is powerful and impressive to one's colleagues. However, even an experienced dysmorphologist can be wrong if one is too quick to make a diagnosis, as many findings are common to multiple disorders. Therefore, a careful and complete exam is warranted even in apparently obvious cases. Starting with the "big picture" is a useful approach, however, for examining each body region if followed by sequential evaluation of smaller component subunits within that region (Hall, 1993).

4. Components of the physical exam

When examining the patient's physical characteristics, it is important to be systematic and thorough. Growth parameters (i.e., head circumference, height, and weight) should be recorded on all patients, including adults. The general appearance and behavior of a patient should also be carefully observed. Many genetic disorders have characteristic behaviors that may have as much diagnostic importance as any physical finding. Examples include spontaneous laughter in patients with Angelman syndrome, self-hugging in patients with Smith–Magenis syndrome, and excessive anxiety with a friendly personality in patients with Williams syndrome (Cassidy and Morris, 2002).

A useful regional approach is to start with examination of the head and proceed downward. Greatest attention is given to examination of the head and face, as this is where the greatest variability of human features is seen. Assessing symmetry, placement, and proportions both of overall appearance and of all paired structures (e.g., eyes and ears) may detect differences not otherwise appreciated. The skull should be observed for symmetry and contour, then palpated for ridging of sutures and fontanel sizes. The forehead should be evaluated for contour and breadth. The placement, rotation, size, and configuration of the ears should be noted, as should the presence of preauricular pits or tags. The eye distances should be measured. The external eye should be evaluated for unusual position or structural abnormalities of the lids, irises, or pupils. Ophthalmologic evaluation for cataracts or retinal abnormalities should be attempted. The nose should be evaluated for the configuration of the nasal bridge and tip, as well as symmetry of the nasal septum. The configuration of the philtrum should be noted, along with the size of the mouth and any unusual features of the lips. The arch of the palate should be observed, along with any cleft of the palate or uvula. Teeth should be evaluated for size, placement, and abnormalities of enamel or configuration. In addition, the profile should be assessed for prominence or recession of the forehead, eyes, midface, and chin. Any redundancy of nuchal skin should be noted. Finally, a description of hair, eyebrows, and eyelashes should include assessment of texture, color, thickness, and length.

Evaluation of the trunk includes measuring relative proportions of upper and lower segment lengths (as divided at the symphysis pubis), sternal length, chest circumference, and internipple distance. The chest, clavicles, ribcage, and spine should be examined for deformity or abnormalities of contour. The positioning and form of the nipples and sternum should be observed. Any heart murmur, abdominal

wall defect, or organomegaly should be noted. Sacral spinal defects such as hair tufts or pits should be noted. Examination of the genitalia should include assessment of proper proportions and positioning of structures, as well as Tanner stage.

Careful examination of the extremities can also yield useful diagnostic clues. The relative proportions and symmetry of the various segments of each limb should be noted, as specific abnormalities may indicate a particular skeletal dysplasia. All joints should be assessed for contractures, abnormal angulation, or hypermobility (preferably using the Beighton score) (Beighton *et al*., 1997, 1998). Examination of the hands and feet require careful consideration, as they offer a wide range of insight into early fetal development. Measurements should be made of total hand, palm, middle finger, and foot lengths. Fingers and toes should be assessed for placement, contractures, webbing, and spacing. The contour of the soles of the feet should be noted. Careful observation should also be given to the texture and configuration of fingernails and toenails. For example, subungual fibromas may be the presenting sign of Tuberous Sclerosis in a patient with mental retardation and seizures.

The skin should be carefully examined in an effort to detect and describe any birthmarks or abnormalities in pigment, texture, elasticity, or wound healing. This may require using ultraviolet light in fair-skinned individuals. Observing dermatoglyphic patterns and skin creases is also important. Some conditions have characteristic dermatoglyphic patterns, as exemplified by a predominance of fingertip whorls in Smith–Lemli–Opitz syndrome. More generally, abnormal skin creases reflect an abnormality in early fetal movement before 18 weeks' gestation.

5. Placing the physical exam in context

Information obtained from a detailed medical and family history will often guide the physical exam, allowing one to focus extra attention on specific findings (*see* Article 78, **Genetic family history, pedigree analysis, and risk assessment**, Volume 2). For example, a postpubertal male referred for evaluation of mental retardation should be assessed for large ear size and macroorchidism, features that would raise suspicion for fragile X syndrome. Similarly, using background knowledge will allow one to direct attention to features that may have been missed. For example, the examination of an infant with ambiguous genitalia should include careful analysis of the toes, as cutaneous syndactyly (webbing) between the second and third toes in this context would raise suspicion for Smith–Lemli–Opitz syndrome.

Examining a patient's family members and/or reviewing their photographs can establish the background features that may assist the examiner in understanding where their patient's features might have originated. In particular, any parameter thought to be abnormal in the patient should be examined in their relatives.

A final point to consider is that physical findings change with time in many genetic syndromes. In Prader–Willi syndrome, for example, affected newborns are hypotonic and manifest failure to thrive, but within several years they become hyperphagic and obese (*see* Article 29, **Imprinting in Prader–Willi and Angelman syndromes**, Volume 1). Periodic evaluations are important in cases in

which a diagnosis cannot be reached, as physical examination findings may have changed into a recognizable pattern consistent with a known diagnosis. Similarly, reviewing photographs of a patient at various ages may detect phenotypic features classic for a particular condition that are no longer recognizable.

Genetic testing and genotype–phenotype correlations

Elfride De Baere
Ghent University, Ghent, Belgium

Ludwine Messiaen
University of Alabama at Birmingham, Birmingham, AL, USA

1. Introduction

In the wake of the Human Genome Project, thousands of genes involved in monogenetic Mendelian disorders have been cloned, allowing identification of the germ-line mutation (genotype) underlying the specific features in an affected person (phenotype). It was expected that knowledge of mutations would lead to consistent genotype–phenotype correlations, clarifying why a given genetic change results in a particular clinical phenotype. Elucidation of genotype–phenotype correlations would move clinical genetics toward predictive medicine, allowing a prognosis and better selection of therapeutic strategies for any individual patient. However, it has become clear that the correlation between genotype and phenotype is often incomplete. For most "single-gene" disorders, a significant number of mutant alleles do not correlate absolutely with a clinical phenotype because of the effect of additional independently inherited genetic variations and/or environmental influences (Dipple and McCabe, 2000).

Intrafamilial variability can result from a combination of the effects of other unlinked genes (modifier genes, quantitative trait loci), epigenetic factors (skewed X-inactivation, imprinting, methylation, etc.), and environmental factors (nutritional, toxins, drugs, chance events). Interfamilial variability can be enhanced by allelic heterogeneity when many different mutations within a given gene can be seen in patients presenting with a given disease.

To identify genotype–phenotype correlations, the type of mutation must be related to the severity of the disorder and/or the spectrum of features. First, the spectrum of mutations underlying the disorder must be fully understood. The coding region of the gene needs to be analyzed in a large number of patients with a given genetic disease. Mutations can lead to loss-of-function (i.e., decrease or absence of normal gene product, leading to a hypomorphic and null alleles respectively; loss of normal gene function plus antagonistic effect of the mutant gene product with the normal gene product, called *dominant negative effect* or *antimorphic allele*) or gain-of-function (increased or novel function of the protein).

Examples of diseases and disease genes where genotype–phenotype correlations have been observed to some extent are described below.

2. Loss-of-function and gain-of-function mutations in the same gene

In some genes, mutations can lead either to loss-of-function or gain-of-function, resulting in distinct clinical phenotypes.

The *RET* proto-oncogene (MIM 164761) on chromosome 10q11.2 encodes a cell surface tyrosine kinase, consisting of extracellular, transmembrane, and intracellular tyrosine kinase domains activating signal transduction. Mutations that cause loss-of-function (total gene and small intragenic deletions, nonsense mutations, and splicing mutations resulting in a truncated protein) result in Hirschsprung disease (MIM 142623), a congenital disorder characterized by the absence of enteric ganglia along a variable length of intestine. In contrast, mutations that cause gain-of-function effect result in either multiple endocrine neoplasia type 2A or 2B (MEN 2A/2B) (MIM 171400/162300), characterized by a high incidence of thyroid carcinoma and phaeochromocytoma. MEN2A patients have, in addition, an increased risk for parathyroid adenoma, and MEN2B patients develop mucosal neuromas, ganglioneuromatosis of the gastrointestinal tract, and a "Marfanoid" habitus. The activating mutations causing MEN 2A are clustered in five cysteine residues in the extracellular domain, while MEN 2B is caused by a unique mutation (M918T) in the tyrosine kinase domain (Edery *et al*., 1997) (Figure 1).

Fibroblast growth factors (FGF) play key roles in embryogenesis. The transduction of extracellular *FGF* signals is mediated by a family of four transmembrane tyrosine kinase receptors: the fibroblast growth factor receptors (FGFR), each of which contains an extracellular region with three immunoglobulin-like domains, a transmembrane segment, and two intracellular tyrosine kinase domains (Figure 2).

A dominant gain-of-function mutation of *FGFR1* (MIM 136350) underlies a form of craniosynostosis (Pfeiffer syndrome, MIM 101600) (Muenke and Schell,

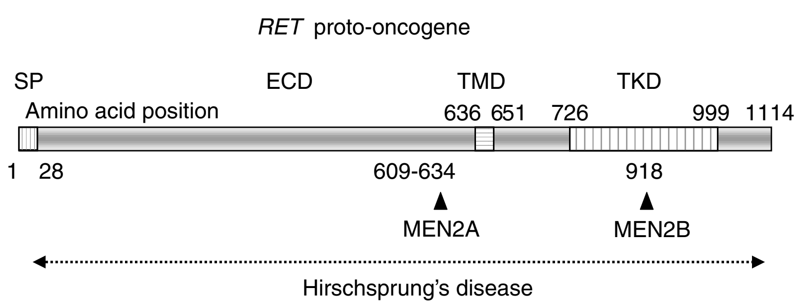

Figure 1 The *RET* proto-oncogene and its genotype–phenotype correlations. On top, the structure of the RET proteins is shown. Numbers represent amino acid residues. The most common mutation sites in different clinical entities are shown by arrows. Abbreviations used: SP: signal peptide; ECD: extracellular domain; TMD: transmembrane domain; TKD: tyrosine kinase domain; MEN2A and 2B: multiple endocrine neoplasia type 2A and 2B

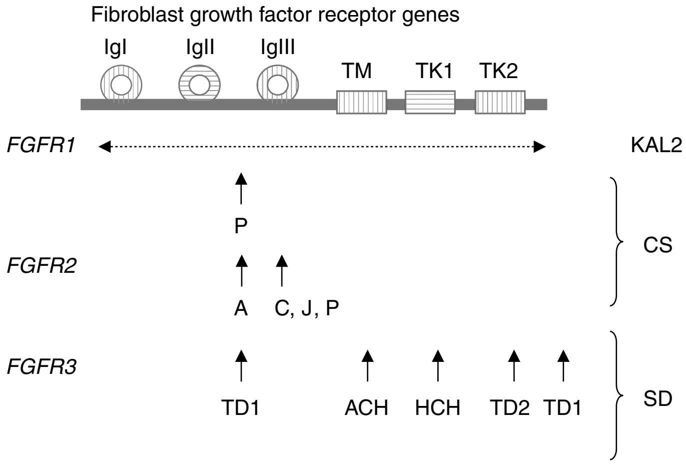

Figure 2 Fibroblast growth factor receptors (FGFR) and their genotype–phenotype correlations. On top, the structure of the FGFR proteins is shown. Arrows indicate the location of mutations with respect to the developmental disorders they cause (craniosynostosis syndromes, skeletal dysplasias, and autosomal dominant Kallmann syndrome). Abbreviations used: KAL2: autosomal dominant Kallmann syndrome; CS: craniosynostosis group; SD: skeletal dysplasia group; P: Pfeiffer; A: Apert; C: Crouzon; J: Jackson–Weiss; TD: thanatophoric dysplasia; ACH: achondroplasia; HCH: hypochondroplasia

1995). In contrast, a dominant form of Kallmann syndrome (KAL2, MIM 147950), characterized by hypogonadotropic hypogonadism and anosmia, results from loss-of-function mutations in *FGFR1* (Dode *et al*., 2003) (Figure 2).

Apert syndrome (MIM 101200), characterized by craniosynostosis and typical syndactyly, is caused by a mutation in one of the adjacent *FGFR2* (MIM 176943) residues that link the second and third immunoglobulin loops. In contrast, mutations in the third immunoglobulin loop cause either Crouzon syndrome (MIM 123500), in which the limbs are normal, or Pfeiffer syndrome (MIM 101600) (Muenke and Schell, 1995) (Figure 2).

In achondroplasia (MIM 100800), the limbs show proximal shortening and the head is enlarged. About 98% of achondroplasia patients carry the mutation 1138G>A (Gly380Arg) and 1% 1138G>C (Gly380Arg) in the transmembrane domain of *FGFR3* (Figure 2). Hypochondroplasia, a milder form of skeletal dysplasia, is caused by mutations in the proximal tyrosine kinase domain of *FGFR3*. Finally, the lethal thanatophoric dysplasia is caused by mutations in either the residues linking the second and third immunoglobulin domain of *FGFR3*, or the distal *FGFR3* tyrosine kinase domain (Muenke and Schell, 1995) (Figure 2).

3. Trinucleotide repeat expansion

A classical example of genotype–phenotype correlations is found in myotonic dystrophy (DM) (MIM 160900), a disorder affecting skeletal and smooth muscle, the eye, heart, endocrine system, and central nervous system. It presents in three

overlapping clinical phenotypes (mild, classical, congenital). The diagnosis is confirmed by detection of a CTG trinucleotide repeat expansion in the 3′ UTR of the *DMPK* gene on 19q13.2-q13.3 (MIM 605377). The number of CTG repeats ranges from 5 to 37 on normal alleles. Individuals with 38–49 CTG repeats do not have disease symptoms, but their children are at risk to have inherited a larger repeat size (anticipation). Persons with a number of CTG repeats >50 to ∼150 are frequently mildly affected, developing cataract and mild myotonia. Patients with repeats between 100 and ∼1000/1500 have classical MD with an age of onset between 10 and 30 years, presenting with weakness, myotonia, cataracts, balding, and cardiac arrhythmia. The average age of death is between 48 and 55 years. In the severe congenital form, neonats present with infantile hypotonia, respiratory deficits, and mental retardation. These patients typically have ∼1000 to >2000 CTG repeats. The average age of death is 45 years (Tapscott and Thornton, 2001). Expansion of the CTG repeat may affect processing of the primary transcript, or may affect expression of a whole series of genes by altering chromatin structure in this gene-rich chromosomal region (Klesert *et al*., 1997).

4. Loss-of-function

4.1. X-linked recessive conditions

Duchenne and Becker muscular dystrophy (DMD/BMD) (MIM 310200/300376) are progressive severe skeletal muscle disorders, caused by mutations in the *DMD* gene located at Xp21.2 (MIM 300377). DMD usually presents in early childhood and is rapidly progressive, with affected children becoming wheelchair-bound by age 12 years. Few patients survive after the third decade. The milder BMD is characterized by later-onset skeletal muscle weakness. The average age of death is after 40. The phenotypes are best correlated with the degree of expression of dystrophin. In general, DMD is caused by frameshift or nonsense mutations leading to a severely truncated dystrophin protein. Frame-neutral mutations, resulting in a shorter than normal dystrophin protein molecule and a residual production of dystrophin, generally cause BMD. More than 70% of disease-causing alleles consist of the deletion or duplication of one or more exons, but also total gene deletions and small intragenic mutations occur (Muntoni *et al*., 2003).

4.2. Haploinsufficient conditions and lack of genotype–phenotype correlations

Loss-of-function mutations leading to a dominant condition are referred to as *haploinsufficient*, prevalent in dosage sensitive genes (e.g., genes coding for transcription factors). Haploinsufficiency conditions often show variable expression and lack of genotype–phenotype correlation, as the changes in gene dosage depend on interactions that are subject to modifications elsewhere in the genome.

Neurofibromatosis type 1 (NF1, MIM 162200) is a progressive autosomal dominant neurocutaneous disorder notorious for its phenotypical intra- and interfamilial

variability. It is caused by mutations in the *NF1* gene on chromosome 17. The extreme allelic heterogeneity, added to the size and complexity of the gene, further complicates the search for genotype–phenotype correlations in this disorder. So far, the only genotype–phenotype correlation identified concerns the whole-gene deletion phenotype, being more severe with more neurofibromas at an earlier age, a lower average IQ, facial dysmorphisms, and an increased risk for the development of malignant peripheral nerve sheath tumors. These findings have led to speculation on modifiers of the haploinsufficient state of the NF1 gene product neurofibromin (Easton *et al*., 1993; Viskochil, 2002).

5. Concluding remarks

Now that many genes causing Mendelian disorders have been identified, the study of genotype–phenotype correlations has moved to center stage. However, with the collection of mutation data in "single-gene" disorders, geneticists have observed that the correlation between genotype and phenotype is often inconsistent or incomplete. The frequent lack of correlations supports the notion that a mutant gene product is part of a complex system in which tissue-specific alternative splicing, intragenic SNPs, epigenetic changes, protein–gene and protein–protein interactions, modifying genes, and environmental factors play a role.

The insight that "simple" Mendelian traits are in fact complex traits has consequences for families and their physicians, and is a challenge for the scientific community. Hence, there is a strong clinical and scientific motivation to identify factors playing a role in genotype–phenotype correlations.

Genetic counseling process

Gretchen H. Schneider
Harvard Medical School-Partners Healthcare Center for Genetics and Genomics, Boston, MA, USA

1. Introduction

Genetic counseling was first defined in 1975 when an ad hoc committee of the American Society of Human Genetics described it as a "communication process which deals with the human problems associated with the occurrence or risk of occurrence of a genetic disorder in a family". The committee went on further to explain that genetic counseling includes helping a patient or family (American Society of Human Genetics, 1975):

1. understand a diagnosis, its likely course of action, and treatment possibilities;
2. appreciate the hereditary nature and the risks to family members;
3. be aware of the options for dealing with risks involved;
4. choose an appropriate course of action;
5. make the best adjustment to the disorder or risk to family members.

This original explanation has remained a valid description and is still widely disseminated. It is important to recognize, however, that the genetic counseling process often begins before a diagnosis or precise risk is determined, and thus also encompasses the steps involved in the collection and assessment of information relevant to the questions being addressed in the genetic counseling session.

Genetic counseling is often aimed at answering a question such as: What is wrong with me (my child)? How did this happen? Is my pregnancy at risk for a specific disease? Should I have genetic testing? Am I at risk for cancer due to my family history?

2. Information collection

The first step in answering such a question is gathering information so that precise and accurate predictions can be made. This should include a complete pregnancy, medical, and family history (*see* Article 78, **Genetic family history, pedigree analysis, and risk assessment**, Volume 2) on the patient(s). Information from medical records on the patient or family members may be necessary to clarify

or verify what is obtained during the session. A physical examination by a clinical geneticist (*see* Article 79, **The physical examination in clinical genetics**, Volume 2) may also be an important means of assessing whether evidence of a genetic disease is present. In some cases, review of medical literature in databases, textbooks, or journals will allow comparison of findings in the patient to what has been described in other individuals. Finally, additional testing or evaluations by other specialists might also be warranted and provide additional data pertinent to the patient's assessment.

3. Assessment

Synthesis of information gathered as part of the genetic evaluation will hopefully allow for either a diagnosis to be made or a calculation of risk for a patient or family. This will, in turn, facilitate the discussion of its implications as part of the genetic counseling process. The accuracy of any assessment is dependent on many factors. In the case of a diagnosis, those made based on clinical findings (for example, a child who has features suggestive of Bardet Biedl syndrome) are more dependent on clinical interpretation than one confirmed by a genetic test (for example, the identification of two *CFTR* mutations in someone with clinical features of cystic fibrosis). In situations in which the assessment entails providing an estimate of risk, it is crucial that the risk is derived using precise information that may include, but not be limited to, accurate history, confirmation of diagnoses in family members, or solid data from the literature. This will allow for provision of numbers that truly reflect the risk to the patient or family. If an assessment is not based on complete or correct information, then this may result in decisions being made based on erroneous data.

4. Discussion

As stated in the formal definition of genetic counseling above, a detailed explanation of what is determined in the assessment is a critical part of the genetic counseling process. When a diagnosis has been made, this should include: what the disease is, how the diagnosis was established, how a disorder manifests over a period of time, what interventions are available for affected individuals, what the underlying hereditary nature is, and whether other family members are at risk of having the same disorder. If a genetic risk is being discussed, the information provided should encompass: what the risk is, how this risk was determined, whether there are limitations to the risk estimate (for example, is it an empiric number from the literature that represents an average), and what types of options are available for reducing the risk (such as prenatal diagnosis in future pregnancies).

Given both the complexities and the potentially sensitive nature of genetic information, it is important that discussions be done in a respectful manner. Explanations should be in a language that the patients or families can understand, and efforts should be made to determine the extent to which they comprehend what is discussed. Care should be taken to give patients time to absorb the information and ask questions. If possible and when appropriate, children should be excluded from

the discussion so that parents can focus on what is being said and ask questions openly without worry of information being misunderstood by children. Finally, written documentation should be sent to the patient or family after the genetic counseling visit for them to have as a summary.

5. Decision making

In many cases, particularly in the prenatal setting, genetic counseling for patients or families culminates in their having information on which to base decisions. Should we pursue carrier testing? How can we reduce the recurrence risk for future children? Do we want prenatal diagnosis? Therefore, an important component of a genetic counseling session includes discussion of what choices a patient or family has based on the information that has been provided to them. In some situations, for example, a clinical diagnosis for which there is no genetic testing and more than one inheritance pattern, testing other pregnancies is not an option. For others, however, the possibility of reliable carrier testing, accurate prenatal diagnosis, or alternatives such as egg or sperm donation, adoption, or preimplantation genetic diagnosis may be available and should be presented to families as ways of dealing with the risks quoted to them.

It is crucial to recognize that the decision-making process in a genetic counseling session can be different for different persons. One couple in which the woman is of advanced maternal age may clearly want an amniocentesis, whereas for others in the same situation, the decision may not be as straightforward. One couple may choose to have carrier testing for cystic fibrosis based on ethnicity, while others would decline. In any situation, the discussion should be unbiased and in-depth to include a review of all possible options (testing vs. not testing, and the limitations of both), testing outcomes (abnormal, normal, inconclusive) and subsequent actions (testing options for future pregnancies or termination or continuation, in the case of an ongoing pregnancy). For those having difficulty in choosing a course of action, it can be helpful to have patients go through the different scenarios so that they can sort out their feelings and best select their next step. Even having done this, though, some couples are left having difficulty in making a decision.

Genetic counseling has traditionally been defined as nondirective, where the genetic counselor provides information so the patients can make the best decision for their own particular situation. The goal is not to tell the patients what to do, but to encourage patient autonomy so that he or she is able to select an appropriate course of action. Recent discussions in the field, however, now question nondirectiveness as the central feature of genetic counseling, claiming nondirectiveness is ill-suited in many situations (Biesecker, 2003; Kessler, 1997; Weil, 2003). Regardless, the objectives in any genetic counseling remain unchanged: providing information, facilitating decision making, and offering support in a way that is customized to every individual situation.

6. Support

Genetic counseling would be inadequate without psychological assessment and support for patients or families going through the process. While the extent to which

this is needed varies by situation and by family, most situations call for some type of intervention at some point during the patient's or family's coming to terms with a genetic disease or risk. This may include ongoing assessment of their ability to cope with their situation and acknowledgment and validation of the feelings that they are experiencing. For those who are continually struggling, the genetic counselor may be called on to identify additional resources for therapeutic interventions that lay outside the scope of their expertise. Other families may be in need of information on a disease-specific foundation or support group or be interested in speaking with other families struggling with the same issues. Provision of these services is part of the ongoing nature of the genetic counseling process. Finally, merely remaining available as a source of information or to address questions or concerns can be of great help to patients and families.

7. Conclusion

As research on the human genome continues to unravel the molecular basis of genetic disease, genetic counseling will only grow in importance as well as become more complicated. Advanced technologies will translate to better testing options than those that now exist. Knowledge of previously poorly defined diseases will allow us to better diagnose, manage, and assess risk for other family members. Perhaps most importantly, increased understanding of the underlying genetic basis for common disorders will likely result in a more widespread use of genetic testing to determine predisposition to many diseases. This promises to not only change the field of genetics but also revolutionize all areas of medicine.

Treatment of monogenic disorders

Maria Descartes and Joseph R. Biggio Jr
University of Alabama at Birmingham, Birmingham, AL, USA

1. Introduction

Although molecular genetic technology has yet to realize its potential for the large-scale cure or treatment of disease, it has provided important new avenues of therapy for single gene disorders by replacing or restoring the function of defective proteins or by minimizing the consequences of the protein deficiency (Nussbaum *et al*., 2001). According to a 1985 study of inborn metabolic errors, the monogenic disorders most frequently targeted for such therapy, only 12% of patients demonstrated a complete response to such treatment, with partial benefits seen in 40% and no response at all in 48% (Hayes *et al*., 1985). In a 1997 study, the rate of complete response remained stable at 12% but the rates for partial or nonresponsiveness changed to 54% and 34% respectively (Treacy *et al*., 2001). Though the stagnant complete response rate signals that complete cure of monogenic disorders has remained an elusive goal, the higher proportion of partial responses marks real progress in controlling and reducing the symptoms associated with them. (Data from Journal of Medicine, **www.wiley.co.uk/genmed/clinical**, updated January 2004.)

Two main treatment options exist for monogenic disorders. First, symptoms may be treated as they occur, with alterations to the milieu to minimize future symptom occurrence. Second, the functioning of the defective protein can be enhanced or the defective protein can be bypassed or replaced altogether.

Changes intended to reduce the incidence of symptoms may be accomplished pharmacologically, surgically, or environmentally. For example, certain medications may be avoided that precipitate porphyric crises, displaced extremities in those with distal arthrogryposis may be splinted or surgically corrected, and smoke-filled environments may be avoided by those with cystic fibrosis.

2. Dietary modification

For inborn metabolic errors, the archetype for monogenic disorders, treatment of this type is targeted at restricting dietary intake, increasing excretion of problematic substances, providing deficient substances, or altering the primary metabolic rate

(Scriver and Treacy, 1999). For example, mental retardation in phenyketonuria patients can be avoided or made less severe by restricting the dietary intake of phenylalanine, an essential amino acid. Dietary restriction has also been used to successfully treat urea cycle disorders, several organic acidemias, and maple syrup urine disease. However, the limited understanding of the metabolic pathways involved in disease progression still poses a barrier to effective treatment, as can be seen in the partial response to treatment by patients with galactosemia; despite a reduction in the occurrence of cataracts and mental retardation, females with this disorder invariably experience premature ovarian failure (Guerrero, 2000).

3. Alternative elimination

For disorders characterized by accumulation of a toxic precursor or by-product, excretion of the offending substance is the preferred therapeutic method. Alternative pathways can be activated, allowing the harmful substance to be converted to a benign form that can be excreted. Pharmacologic agents such as sodium benzoate, phenylbutyrate, or phenylacetate can be used in patients with urea cycle disorders to promote nitrogen elimination and avoid the toxic accumulation of ammonium ion. Additional clearance mechanisms have been employed in disorders characterized by a failure to excrete excess amounts of substrate. Chelating therapy with penicillamine has been used to increase excretion of copper in Wilson disease, and serial phlebotomy has been preferred over chelation to remove the excess iron that characterizes hemochromatosis.

4. Metabolite replacement

Replacement of a deficient metabolic product can also be an effective therapeutic tool in certain disorders. For example, the number of hypoglycemic episodes suffered by patients with Type I and Type III glycogen storage disorders can be reduced by encouraging them to eat frequently and to ingest cornstarch, a slowly digested glucose polymer that provides a sustained glucose source. Cholesterol supplementation has provided at least some benefit to patients with Smith–Lemli–Opitz syndrome, a disorder due to impaired cholesterol biosynthesis (Irons, 1997). Therapeutic measures of this type have also been applied to many endocrine disorders. The defects responsible for congenital adrenal hyperplasia are the prototype of this type of therapy; patients deficient in 21-hydroxylase, as well as other enzymes in this pathway, do not produce sufficient cortisol to trigger feedback inhibition, leading to increased levels of adrenocorticotrophic hormone (ACTH). Because of the metabolic block, cortisol precursors are shunted to the androgen production pathway and result in masculinization. This overproduction of sex steroids and the resulting masculinization have been successfully prevented both pre- and postnatally by replacing the deficient glucocorticoid using pharmacologic agents such as dexamethasone (Pang *et al*., 1990).

5. Enzymatic blockade

In some inborn metabolic disorders, the detrimental effects are due not to the defect in the primary metabolic pathway that results in the lack of a needed product but to a metabolite produced by an alternative pathway. In such cases, therapy has focused on inhibiting the normal pathway at an early stage to prevent the enhancement of the alternative pathways. For example, in Type I tyrosinemia, the lack of the enzyme fumarylacetoacetate hydrolase results in the accumulation of fumarylacetoacetate and maleylacetoacetate, which are then metabolized via an alternative pathway to succinylacetone, a toxic metabolite responsible for many of the neurologic symptoms of this disorder. Treatment with NTBC (2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione) results in the inhibition of hydroxy-phenyl pyruvate dioxygenase and the blockade of the metabolic pathway at an early stage, leading to dramatic decreases in succinylacetone levels. Because this therapy leads to an accumulation of tyrosine, dietary restriction of tyrosine and phenylalanine are typically instituted jointly with NTBC therapy (Lock, 1998). Allopurinol therapy has similarly been used for the prevention of uric acid accumulation in patients with Lesch–Nyhan syndrome. Normal processes of feedback inhibition can also be exploited to turn off enzyme systems that result in accumulation of toxic substances. In acute intermittent porphyria, hematin therapy during an acute porphyric crisis decreases the activity of δ-aminolevulinic acid synthetase and thereby reduces porphyrin production (Watson *et al*., 1978).

6. Enzyme potentiation

As an alternative to the milieu-altering treatments designed to reduce symptoms outlined above, the functioning of the defective protein can be enhanced by facilitating its binding to a vitamin cofactor. Such binding is known to be a key step in the activation and regulation of many metabolic pathways, including those involved in congenital lactic acidosis, organic acidemias, and homocystinuria. For example, the activity of the enzyme pyruvate dehydrogenase is enhanced by the cofactor thiamine. Indeed, an altered form of the enzyme, which shows a decreased affinity for thiamine, is observed in conditions characterized by a deficiency of the enzyme, such as congenital lactic acidosis. In some patients suffering from this disorder, supra-pharmacologic doses of thiamine have increased the enzymatic activity by forcing thiamine binding (Naito *et al*., 1994). Similarly, excess biotin has been used successfully for holocarboxylase deficiency, excess thiamine for homocystinuria due to cystathionine β-synthetase deficiency, and excess vitamin B12 for some types of methylmalonic acidemia (Morrone, 2002).

7. Enzymatic bypass

Alternatively, the defective protein can be bypassed. Because an adequate supply of cofactors for further enzymatic reactions is dependent upon recycling reactions,

enzymatic defects leading to inadequate recycling can deplete cofactor stores and disrupt metabolism. Some of these defective enzymes do not play a significant role in other metabolic pathways and so cofactors can simply be replaced under certain conditions. For example, administration of pharmacologic doses of biotin can virtually reverse the depletion of biotin seen when biotinidase, the enzyme responsible for the removal of the cofactor biotin from the active form of a carboxylase enzyme, is deficient. Likewise, high doses of folic acid can bypass the insufficient recycling caused by defects in folic acid metabolism and prevent the hypomethioninemia and hyperhomocystinemia resulting from depleted folate stores and decreased methyl donors.

8. Protein replacement

Finally, the entire defective protein can be replaced. Protein replacement can be accomplished, at least theoretically, via three different strategies: (1) actual administration of the wild-type/normally functioning protein, (2) transplantation of cells or tissues that produce the normal protein, or (3) gene therapy in which only the affected gene is introduced via a vector.

In the first strategy, a normal protein is administered to replace the defective one. Such protein replacement has thus far been applied successfully only to a small number of conditions because the administered protein must reach its site of normal activity in order to achieve normal function. That requirement may be formidable when proteins need to cross the blood–brain barrier to function in the central nervous system. Thus, excellent clinical responses to enzyme replacement therapy have been reported for some lysosomal storage disorders such as nonneuronopathic Gaucher disease and Fabry disease, but only limited responses have been seen in neuronopathic Gaucher disease and Hurler syndrome, because the accumulated toxic metabolites within the nervous system remain relatively inaccessible to the infused protein (Brady *et al*., 2001). In addition to problems of delivery to the normal physiologic compartment, the stability, pharmacokinetics, and antigenicity of the administered medications must be considered (Barranger and O'Rourke, 2001). In many disorders, because the mutant protein may be missing key antigenic sites or have an altered conformation, the normal protein, when introduced, may be recognized by the immune system as "nonself" or foreign and trigger an immune response, thereby not only increasing the risk of infusion reactions but also decreasing the stability of the protein and necessitating an escalation of dose in order to maintain therapeutic results (Kakkis *et al*., 2001).

The second strategy for protein replacement seeks to bypass the repeated administrations required by protein infusion therapy by exploiting the more long-lasting benefits provided by tissue and organ transplantation. Both solid organ transplants, such as liver transplants for ornithine transcarbamylase deficiency, and bone marrow transplants, such as those for Hurler syndrome, have been performed to provide a sustained source of the previously deficient protein. While both have been able to provide sufficient quantities of protein to ameliorate many symptoms, the protein, like the endogenously produced protein, must still penetrate all the physiologic

compartments necessary to arrive at its locale of normal activity. Because the transit of the blood–brain barrier can be problematic for large proteins and because transplantation of tissue directly into the central nervous system is not feasible, the utility of bone marrow and organ transplantation in the treatment of lysosomal storage disorders associated with the accumulation of toxic metabolites in the central nervous system remains uncertain. For example, while bone marrow transplants have resulted in an improvement in hepatosplenomegaly and cardiac function in patients with Hurler syndrome, the neurologic symptoms often remain unabated (Peters *et al*., 1998).

One potential tool for the treatment of monogenic disorders is a modality that seeks to replace the defective protein by reactivation of silent or poorly expressed genes. The end result of this "transcriptional therapy" is an increase in the number of mRNA signals produced from the target genes. In vitro and in vivo studies have demonstrated reactivation of several genes by "transcriptional therapy", including ALDPL1, SMN2, and fetal hemoglobin, but, with the exception of the induction of gamma globin chain expression by hydroxyurea, these techniques have yet to be applied clinically (Chiurazzi and Neri, 2003; Bunn, 1997).

Third, gene therapy has been investigated as a means of providing a renewable protein source. Disorders resulting from a simple deficiency of a specific gene product are generally the most amenable to treatment because even low-level expression of an introduced normal allele should be sufficient to overcome the deficiency. While, in principle, this approach seems straightforward, it has encountered the by now familiar obstacle of protein accessibility to diseased tissue as well as problems in the regulation of gene expression. In addition, the efficacy of such treatment requires not only a wild-type form of the protein but also the presence in any transfected tissue of all cofactors and enzymes necessary for the production of mature functional protein.

Gene therapy has been used for monogenic disorders only in the absence of other therapeutic options or, as is the case with severe combined immunodeficiency syndrome, when the disorder is severe enough to warrant the risks. The development of effective gene therapies for protein replacement has been hampered by the attendant risks, which include an adverse reaction to the vector or transferred gene, the potential induction of a mutation in the patient's germ line, and the potential integration of the transferred gene into the patient's DNA, resulting in activation of a proto-oncogene, disruption of a tumor-suppressor gene, or the disruption of an otherwise normal, essential gene.

In summary, the tremendous progress made over the last quarter of a century in understanding the pathophysiologic basis of many monogenic disorders has facilitated the development of more effective palliative therapies, but the quest for the ultimate therapy utilizing molecular techniques to replace or repair the defective gene remains ongoing.

Carrier screening: a tutorial

Wayne W. Grody
David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

Jean A. Amos
Molecular Genetics Specialty Laboratories, Valencia, CA, USA

1. Obstetrical visit and rationale for carrier testing

John and Judy Brown are seeing their obstetrician for a routine prenatal visit; Judy is now 11 weeks pregnant. In taking the family history (Figure 1), the obstetrician notes that John had a brother who died of cystic fibrosis (CF) many years ago in childhood. His condition was characterized by failure to thrive, short stature, malabsorption, and chronic obstructive lung disease. John and Judy are both non-Jewish Caucasians of European descent. Unlike John, Judy has no family history of this disease.

The obstetrician explains that current practice dictates that all pregnant couples be offered CF carrier screening, and that this is even more important when there is a positive family history. The objective of this program is to identify couples at risk so that they can then be offered prenatal diagnosis.

Although it would be helpful to first identify the familial mutations in the affected index case, this is not possible because John's brother is long deceased, and there are no stored tissue specimens; moreover, John initially declined to ask his parents, both of whom are obligate carriers of a familial mutation, to participate in his carrier study. The reason this approach is advantageous is because of the large number of mutations in the *CFTR* gene (over 1300 reported to date). Identification of the mutations in John's brother would allow for more targeted testing of John, as opposed to a generic screening panel. If John were found not to carry either of his brother's mutations, then his carrier risk would be reduced to near zero (assuming proper paternity), and no further testing would be indicated. In contrast, a negative result of screening for a limited subset of mutations in John in the absence of any knowledge of his brother's mutations would still leave him with an appreciable risk of being a carrier (see below) simply because of his family history and our inability to test for all possible mutations in the gene.

Since the familial mutations are not known a priori in this case, both John and Judy are offered screening using the standard panel of 23 mutations as recommended by the American College of Medical Genetics and the American College of Obstetricians and Gynecologists (Grody *et al*., 2001; Watson *et al*., 2004). They

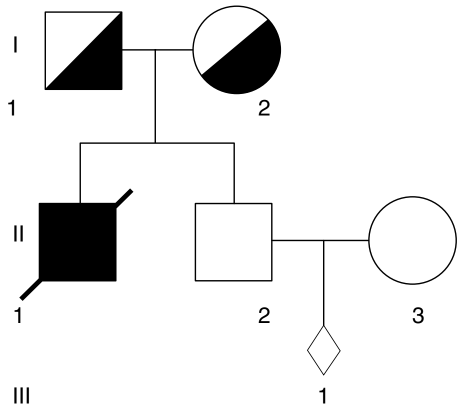

Figure 1 Pedigree of the Brown family indicating John's deceased brother (II-1) who was affected with cystic fibrosis, and Judy's pregnancy (III-1)

consent to proceed, and blood specimens are drawn from both and sent to the Molecular Genetics Laboratory for testing. In two weeks, the couple returns to the clinic to receive their test results and undergo further counseling.

2. Mutation analysis

The prior risk that John is a CF carrier, based on his positive family history, is 2/3. Judy's prior risk is based on the frequency of CF carriers in the Caucasian population, 1/25, since she has no family history of CF. The risk that their fetus has inherited CF is $2/3 \times 1/25 \times 1/4 = 1/150$.

CF mutation analysis is negative for both members of this couple, but the interpretation of these results are very different for each of them, based on their different family histories. The revised CF carrier risk after a negative mutation analysis is based on the prior risk of the individual tested and the rate of detection of carriers in their ethnic group. For both John and Judy, both non-Jewish Caucasians of European descent, this detection rate is 90%. Using Bayesian risk analysis, the testing laboratory reports to the obstetrician that the revised carrier risks for John and Judy are 1/6 and 1/241, respectively, and that the risk to their fetus is 1/5784. The laboratory also encourages the obstetrician to refer this couple for genetic counseling and to request testing of John's parents to identify whether the familial CF mutation(s) are included on the testing panel. On the basis of this recommendation, the obstetrician refers John and Judy to a genetic counselor at the teaching hospital in their city.

3. Genetic counseling and additional mutation analysis

The genetic counselor explains to John and Judy that their negative mutation analyses have reduced the risk of CF to their pregnancy but that identification of the familial mutation might further reduce John's carrier risk and the subsequent risk

of CF to their fetus. John arranges for his parents to submit a blood sample each, and the testing laboratory determines that both are carriers of the most common CF mutation, ΔF508. The laboratory then states that, based on knowledge of the familial mutation, John's revised carrier risk is essentially zero, as is the revised risk to their fetus. John and Judy are reassured by these results and his parents feel gratified that they have contributed to the knowledge that their grandchild's risk to inherit the disease that devastated their own son is extremely low.

4. Comment

In some cases, a couple in which one member has a positive family history elects only to have the partner with the negative family history screened for CF mutations. For the Brown family, this approach would have led to the 1 in 241 carrier risk revision for Judy, and a fetal risk of $2/3 \times 1/241 \times 1/4 = 1$ in 1440, a reduction of almost fivefold from the prior risk. In the authors' experience, many couples find this risk reduction acceptable and do not seek further testing. However, we have seen two couples who have used this approach and have had affected children. Subsequent testing revealed that these affected babies inherited a common mutation from the parent with the affected relative and a rare mutation not included in any US clinical testing panel from the negative family history parent.

Prenatal aneuploidy screening

Katharine D. Wenstrom
University of Alabama at Birmingham School of Medicine, Birmingham, AL, USA

1. Case

Ms FG, a 28-year old white woman currently pregnant at 18 weeks' gestation, is referred for evaluation because an ultrasound exam of her fetus indicated the presence of intracranial cysts. She denied any family history of birth defects, heritable diseases, recurrent pregnancy loss, or infertility, and reported that her pregnancy has been otherwise uncomplicated.

2. Background

Prior to the 1980s, the screening test for fetal aneuploidy was a question: "Will you be age 35 or older when your baby is born?" The basis for this question was the fact that the risk of fetal trisomy, such as Down syndrome or trisomy 18, increases along with maternal age. At age 35, the risk of aneuploidy roughly equals the risk of procedure-related rupture of the membranes leading to pregnancy loss, thus justifying invasive fetal testing (American College of Obstetricians and Gynecologists, 1987). Women who were aged 35 or older were offered definitive fetal diagnosis via either traditional amniocentesis (performed between 14 and 22 weeks' gestation) or chorionic villous sampling (performed between 10 and 13 6/7 weeks). The goal of fetal diagnosis is to give the woman and her partner autonomy; some parents would terminate an affected pregnancy, whereas others would use fetal diagnosis to plan their delivery. For example, foreknowledge that the fetus has trisomy 18, a lethal disorder, would allow the woman to avoid a needless Cesarean delivery for fetal stress in labor (which is common in trisomy 18 pregnancies), since it would not change the neonatal outcome. Foreknowledge of fetal Down syndrome with a cardiac defect would allow delivery conditions to be optimized, for example, by planning delivery at a tertiary center with a pediatric cardiologist available.

A major advance in aneuploidy screening occurred in the 1980s, when it was discovered that the levels of certain maternal serum analytes are altered when the fetus has Down syndrome or trisomy 18 (Haddow *et al*., 1992; Haddow *et al*., 1994). A variety of analytes have been investigated, but the best performing analytes in current use are first-trimester levels of PAPP-A, estriol, AFP, and free β hCG, or second-trimester levels of hCG, estriol, AFP, and inhibin (Wald *et al*.,

1998; Cuckle, 2001). These analytes can be combined with the maternal age-related Down syndrome risk to create either a first- or second-trimester *multiple marker screening test*. For each analyte, the level measured in the woman's serum is compared to the levels found in both normal and Down syndrome pregnancies at the same gestational age. This comparison allows determination of the *relative risk* of fetal Down syndrome associated with each woman's unique analyte level. The individual relative risks associated with each analyte are then combined to create a composite relative risk, and the composite risk is used to modify the woman's maternal age-related Down syndrome risk. Women whose final estimated risk of Down syndrome is above a predetermined cut off – usually 1:200 or 1:270 – are offered definitive (invasive) fetal testing. If all screen-positive women undergo definitive fetal testing, most of the first- and second-trimester multiple marker tests in current use have a 70–75% Down syndrome detection rate at a 5% false-positive rate (Wald *et al*., 1998; Cuckle, 2001). Using a similar protocol, 75–80% of trisomy 18 fetuses are also detected, at a screen-positive rate of 2% (Palomaki *et al*., 1995).

Obstetrical ultrasound equipment has also improved significantly since the 1980s, and currently available machines allow fetal structures to be seen in great detail. Both first- and second-trimester ultrasound exams can now be performed as *sonographic* screening tests for fetal Down syndrome, to identify women at sufficiently increased risk to justify invasive fetal testing. An experienced sonographer can identify anatomic features indicating an increased risk of aneuploidy in up to 87% of Down syndrome fetuses, with a false-positive rate of 13% (Vintzileos *et al*., 1997; Vintzileos *et al*., 1996). Ultrasound also allows detection of 75% of trisomy 18 fetuses; 25% have isolated choroid plexus cysts, and 50% have choroid plexus cysts along with other dysmorphisms or structural anomalies. The false-positive rate for isolated choroid plexus cysts is approximately 0.5% (Gupta *et al*., 1995). Because the majority of fetuses evaluated sonographically are euploid, the negative predictive value of ultrasound for Down syndrome detection is 99.7% (Vintzileos *et al*., 1996). On the other hand, because a proportion of Down syndrome fetuses appear structurally normal on ultrasound, the positive predictive value of ultrasound as a screening test is only 19.4% (Vintzileos *et al*., 1996).

The "genetic ultrasound exam" includes a complete survey of all major anatomic structures as well as evaluation for the presence of dysmorphisms that have been associated with fetal aneuploidy. Such dysmorphisms include choroid plexus cysts, increased nuchal translucency (first trimester) or nuchal thickness (second trimester), presence and size of the nasal bone, an echogenic cardiac focus, renal pelviectasis, echogenic bowel, slightly shortened femur or humerus, hypoplastic middle phalanx of the little finger, and sandal foot (a space between the first and second toes). One aspect of the fetal exam, the measurement of the nuchal translucency or nuchal thickness, requires additional specialized training as well as ongoing monitoring of measurement technique to insure correct assessment (D'Alton *et al*., 2003). The presence of a major structural malformation increases the risk of fetal aneuploidy sufficiently to justify invasive fetal testing; depending on the maternal age, the presence of one or more dysmorphisms may also sufficiently increase the risk. Table 1 lists some common anomalies along with their associated risks of aneuploidy, and Table 2 lists the dysmorphisms most frequently associated with fetal Down syndrome.

Table 1 Malformations associated with fetal aneuploidy

Structural defect	Aneuploidy risk (%)	Most common aneuploidy (trisomy)
Cystic hygroma	60–75	45X (80%); 21,18,13,XXY
Hydrops	30–80	13,21,18,45X
Hydrocephalus	3–8	13,18, triploidy
Holoprosencephaly	40–60	13,18,18p-
Cardiac defects	5–30	21,18,13,22,8,9
Diaphragmatic hernia	20–25	13,18,21,45X
Omphalocele	30–40	13,18
Duodenal atresia	20–30	21
Bladder outlet obstruction	20–25	13,18
Facial cleft	1	13,18, deletions
Limb reduction	8	18
Club foot	6	18,13,4p-,18q-

Table 2 Sonographic dysmorphisms associated with fetal Down syndrome[c]

Ultrasound marker	Incidence ($N = 420$)	Positive predictive value
Structural anomalies (including cardiac)	17 (4%)	7[a]/17 (41.1%)
Short femur	18 (4.3%)	4[a]/18 (22.2%)
Short humerus	16 (3.8%)	7[a]/16 (44%)
Pyelactasis	20 (4.7%)	4[b]/20 (20%)
Nuchal fold thickening $\geq$ 6 mm	15 (3.6%)	9[a]/15 (60%)
Echogenic bowel	4 (1%)	0/4
Choroid plexus cysts	14 (3.3%)	0/14
Hypoplastic/absent mid-phalanx 5th digit	13 (3.1%)	2[a]/13 (15.4%)
Wide space, 1st–2nd toes	4 (1%)	1[a]/4 (25%)
2-vessel umbilical cord	3 (0.7%)	0/3

[a] All cases were associated with additional ultrasound markers.
[b] Three of four cases were associated with additional ultrasound markers.
[c] Reprinted from American Journal of Obstetrics and Gynecology, V87, Vintzileos AM *et al*. The use of second-trimester genetic sonogram in guiding clinical management of patients at increased risk for fetal trisomy 21, pp. 948–952. ©1996, with permission from Elsevier.

Finally, a first-trimester screening test that combines maternal serum analytes with an ultrasound marker has been developed. When evaluated according to a specified protocol, the first-trimester nuchal translucency measurement can be converted to a multiple of the median and used to derive a relative risk; this risk can then be combined with the relative risks associated with PAPP-A and free β hCG, and the ultimate composite risk used to modify the woman's age-related risk. According to the largest multicenter trial, which included more than 33 000 women, this first-trimester test has a Down syndrome detection rate of 80% when the screen-positive rate is held at 3.4%, or 94% when the screen-positive rate is allowed to increase to 10.8% (Malone *et al*., 2003).

3. Approach to this case

A targeted ultrasound exam should be performed, and the patient should be offered the multiple marker screening test; a positive multiple marker screening test should be followed by counseling and consideration of a definitive fetal diagnostic test (Figure 1). In this case, the multiple marker test indicated no increased risk, and

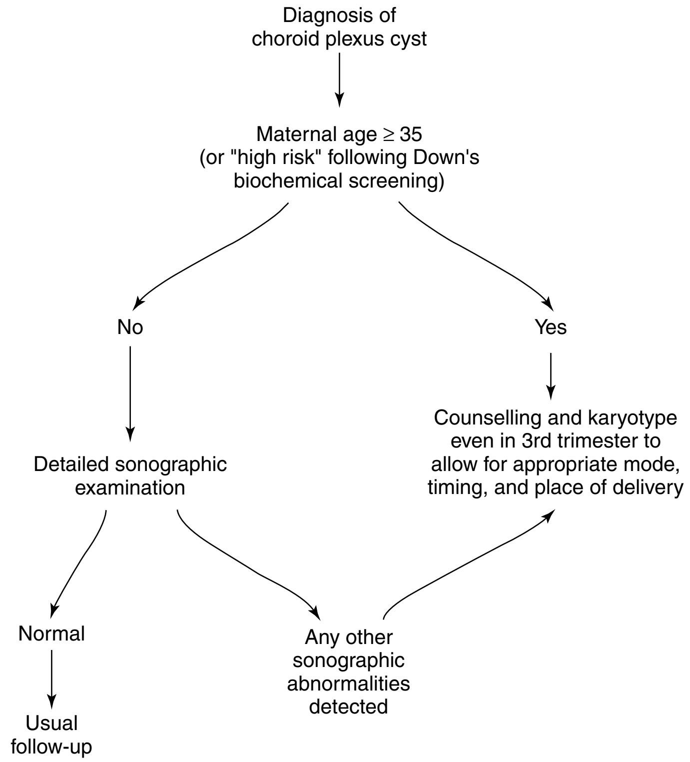

Figure 1 Management plan for suspected choroid plexus cysts (adapted from Gupta JK, Cave M, Lilford RJ, Farrell TA, Irving HC, Mason G, Hau CM (1995) Clinical significance of fetal choroid plexus cysts. *Lancet*, **345**, 724–29)

the targeted ultrasound exam confirmed the presence of choroid plexus cysts. These cysts typically form within the choroid plexus of the lateral ventricles sometime during the first trimester. They usually do not deform or disrupt associated structures, and in most cases resolve completely before delivery. They are of interest mainly because they are found in 4.3% of fetuses with trisomy 18 (Gupta and Lilford, 1997). However, they are also present in 0.47% of euploid fetuses (Gupta and Lilford, 1997). The fetus should therefore be carefully examined to determine if there are any other sonographic features of trisomy 18, such as a ventricular septal defect or another cardiac abnormality, a renal anomaly, clenched fists with the second and fifth fingers overlapping the third and fourth, micrognathia, omphalocele, or rocker bottom feet. In this case, the rest of the fetal exam was normal.

The ultrasound data can then be used to further refine the patient's risk of trisomy 18, using Bayes theorem (Gupta and Lilford, 1997):

$$\text{Posterior risk} = \text{likelihood ratio} \times \text{prior risk} \tag{1}$$

In this case, the likelihood ratio is the relative risk of trisomy 18 associated with isolated choroid plexus cysts. These cysts are found in 4.3% of fetuses with trisomy 18 and in 0.47% of euploid fetuses; the likelihood ratio is thus 4.3/0.47, or 9.04. The prior risk is the maternal age–related risk of trisomy 18 at age 28, or 1:3351. The posterior risk associated with isolated fetal choroid plexus cysts is thus 1:3351 × 9 = 1:371 (The presence of additional fetal abnormalities would have increased her risk by a factor of 1800, to approximately 1:2). Since the most frequently quoted post-procedure loss rate after amniocentesis is 1:200 (American College of Obstetricians and Gynecologists, 1987), the patient's final risk of 1:371 indicates that a procedure-related problem is more likely than fetal trisomy 18. Most patients would decline amniocentesis after considering these relative risks. However, each patient also assigns her own "relative risk", reflecting her personal values, to procedure-related pregnancy loss as well as the birth of a child with trisomy 18. As a result, some women may request amniocentesis even after counseling regarding the relative risk indicated by the ultrasound exam.

Gene identification in common disorders: a tutorial

Mark O. Goodarzi and Jerome I. Rotter
Cedars-Sinai Medical Center, Los Angeles, CA, USA

Elucidation of the genetic determinants of common disorders has proven much more challenging than the genetics of rare conditions (King *et al*., 2002). Whereas a rare genetic disorder is typically caused by a loss- or gain-of-function mutation in one gene that has a dramatic effect on phenotype (for example, the *HUNTINGTIN* gene in Huntington's Disease), common disorders (such as diabetes mellitus, coronary artery disease, or migraine headache) are thought to arise from the complex interaction of variants in several genes and environmental factors (*see* Article 58, **Concept of complex trait genetics**, Volume 2). Each of the several genes contributing to a complex disorder is thought to have only a mild effect on phenotype; it is the combined effect of predisposing genes that contributes to disease. This presents great challenges in terms of identifying these genes; large study populations may be needed to provide enough power to detect genes with a moderate effect on phenotype (*see* Article 68, **Approach to common chronic disorders of adulthood**, Volume 2). In this tutorial, we describe general principles related to gene identification in common disorders.

The first stage is the selection of a disorder that appears to be genetically determined. This is not always straightforward, as common environmental exposures may be misinterpreted as genetic underpinnings. Examination of relatives of probands with a particular disorder is often used to determine whether that disorder has a genetic component; if the disorder occurs at higher frequency in family members than in the general population (familial aggregation), this is evidence for genetic determinants.

The next challenge is to recruit a large number of subjects, on the basis of the specific study design (Figure 1). A case-control study requires a significant number of subjects with the condition and a number of subjects without the condition. Controls must be matched as closely to the cases as possible, differing only in the absence of the condition under study. If the controls differ significantly from the cases in other aspects, for example, ethnic makeup or body composition, then genetic differences between the two may be related to these other factors, a phenomenon referred to as *population stratification*. Family-based studies enroll families based on a proband with the condition of interest. Population stratification is less of an issue when healthy relatives are studied as controls. Often, multicenter collaborations are necessary to successfully recruit a large number of subjects for study.

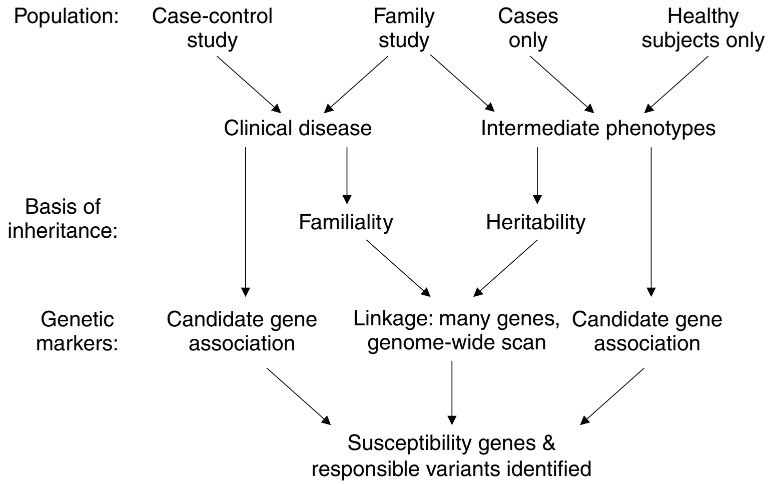

Figure 1 Flowchart illustrating steps in the identification of genes for common disorders

If one has access to only a large group of subjects with a common disorder, genetic studies can be carried out that examine the inheritance of phenotypes that characterize the disorder. For example, diabetes mellitus is characterized by abnormal levels of insulin. If one has only a large number of subjects with diabetes, but no control group, then insulin, rather than the presence or absence of diabetes, can be used as the phenotype in a genetic study. Phenotypes that characterize a disorder are known as component or intermediate phenotypes (also subclinical markers). Intermediate phenotypes can also be studied in subjects who have no overt evidence of disease. In this instance, intermediate phenotypes are thought to be closer to predisposing genes as they may represent the earliest stages of the condition.

Characterization of the traits of the study subjects, that is, phenotyping, is an important feature of genetic studies. At times, one seeks to ask whether a disorder is present or absent. In this case, a precise, reproducible definition of the disorder must be used. Some disorders are difficult to define; in such cases, a definition that is not strict may allow the inclusion of subjects with conditions that resemble each other but do not share genetic determinants. For example, genetic studies of migraine headaches must be careful to exclude other headache disorders. When intermediate phenotypes are to be studied, a balance must be found between the cost of phenotyping and the sophistication of the phenotyping. For example, insulin resistance, a metabolic condition in which the hormone insulin is ineffective in removing glucose from the bloodstream, can be quantified in a number of different ways. Fasting glucose may be used for this purpose and has the advantage of low cost and ease of measurement. On the other hand, insulin resistance may also be quantified by physiologic studies (such as the euglycemic clamp) that involve several hours in a research laboratory for each subject. These are time-consuming, expensive, and technically difficult; however, they yield very reliable measurements. In fact, insulin resistance quantified by physiologic study was found to have a higher heritability than insulin resistance measured by simpler measures (Bergman *et al*.,

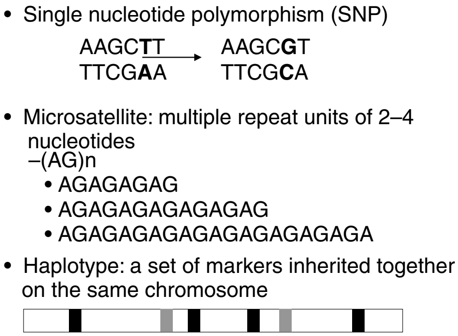

Figure 2 Genetic markers used in studies of common disorders

2003). Thus, the greater difficulty of conducting detailed physiologic phenotyping may yield great benefit in terms of traits that are more genetically determined. This was shown in a study of the lipoprotein lipase (*LPL*) gene, wherein variation in the gene was associated with insulin resistance quantified by a detailed physiologic study, but not with simpler indices of insulin resistance (Goodarzi *et al*., 2004).

Given that we often start with no knowledge of genetic variants that lead to a disease, we must take advantage of markers in the genome. Markers, such as microsatellites and single nucleotide polymorphisms (SNPs, Figure 2), are polymorphic variants interspersed throughout the genome. They are used as tags to track disease-causing variants or mutations. The underlying principle is that markers that are close to disease-causing variants tend to be inherited on the same chromosomes (*see* Article 59, **The common disease common variant concept**, Volume 2). Linkage refers to the situation wherein markers in a region of the genome are inherited in a nonrandom fashion in relation to a particular phenotype. Association refers to the situation wherein a particular allele of a marker is found with greater frequency in those with a particular phenotype. Linkage scans of the entire genome are often carried out using a panel of microsatellites that cover the whole genome. Whole-genome association studies are being contemplated, as genotyping technology advances make such an effort feasible.

A relatively new tool being utilized in the study of common disorders is the haplotype, which is a collection of marker alleles inherited together on the same chromosome. Haplotypes span large regions on the genome, on an average of 10 to 20 kb (Gabriel *et al*., 2002). Haplotypes reflect the global gene structure, encompassing chromosomal blocks that have remained unbroken by recombination during the population history of the gene. The use of haplotypes may be more likely to identify disease-variation associations than is the use of a random single marker. The identification of a haplotype associated with increased or decreased disease risk should facilitate the identification of the actual functional variant that affects disease risk, because this variant should lie on chromosomes identified by that haplotype (Figure 3). A study that examined SNPs within the *LPL* gene did not find any association with coronary artery disease; however, when these SNPs were organized into haplotypes, association with coronary artery disease was evident (Goodarzi *et al*., 2003).

Basic Techniques and Approaches

Uses of databases

Roberta A. Pagon
University of Washington, Seattle, WA, USA

1. Introduction

Databases are used by clinicians practicing genetic medicine and clinical genetics to determine the molecular basis of inherited disorders, establish diagnoses, identify sources and uses of molecular genetic testing, assess and manage inherited cancer risk, provide consumer-health-oriented information to patients, and identify clinical genetic services for geographically dispersed family members. In this chapter, only those databases that are freely available on the Internet and, hence at the point of care, are discussed. Physician use of Medline (**www.ncbi.nlm.nih.gov/pubmed**), a widely used database in the practice of medicine, is assumed.

2. Molecular basis of inherited disorders

OMIM (Online Mendelian Inheritance in Man) (**www.ncbi.nlm.nih.gov/omim**) is funded by the NIH, authored and edited by Dr. Victor A. McKusick and an editorial team at The John Hopkins University, and distributed by the National Library of Medicine (Hamosh, 2002; Maglott *et al*., 2002). OMIM is a timely, authoritative compendium of bibliographic material and observations on inherited disorders, human genes, and gene loci. In May 2004, OMIM had over 15 000 records, including information on over 9000 loci. OMIM is continuously updated with information abstracted from the medical literature; closely integrated with Medline and the NCBI genomic databases; and has extensive links to other genomic databases and resources. OMIM comprises the following:

- *MIM entries:* Descriptive, full-text entries that include approved gene name and symbol, alternative names and symbols in common use, and a loosely structured text description of the disease or gene.
- *OMIM Gene Map:* A tabular listing of the genes and loci represented in MIM ordered pter to qter from chromosome 1-22, X, and Y. The information in the map includes the cytogenetic location, symbol, title, MIM number, method of mapping, comments, and associated disorders and their MIM numbers.
- *OMIM Morbid Map:* Alphabetical listing of disease genes in the OMIM Gene Map organized disease.

- *Clinical synopses:* List of clinical findings in a disease MIM entry by organ system.
- *Mini-MIM:* A text synopsis of an MIM entry.

3. Diagnostic tools

OMIM can be used in a limited way for syndrome identification because of its sophisticated search capabilities by word or phrase that may be a disease name, symptom, or clinical finding. OMIM search results provide a list of entries ranked by the closest match.

4. Sources and uses of molecular genetic testing

GeneTests (**www.genetests.org**), funded by the NIH and developed at the University of Washington, Seattle (Pagon *et al*., 2002), is composed of:

- *Laboratory Directory:* Listing of contact information and test methods for international clinical and research medical genetics laboratories testing for inherited disorders using molecular genetic tests, specialized cytogenetic tests, or biochemical genetic tests. In May 2004, ~600 laboratories testing for ~1050 diseases (~700 clinical; ~350 research only) were listed. Listings are revised as needed and updated every 2 years.
- *GeneReviews:* Disease descriptions that focus on the use of currently available genetic testing in patient diagnosis, management, and genetic counseling authored and peer-reviewed by experts from around the world. Each entry is highly structured and navigable by a Table of Contents. In May 2004, 245 *GeneReviews* were posted; one new one is added each week. Entries are revised as needed and formally updated every 2 years.

The GeneTests hierarchical naming system is used to clarify the evolving understanding of relationships between genes and phenotypes. GeneTests "Disease" search results are displayed as a parent–child hierarchy that relates disease names that refer to a change in a gene ("gene-related" name) to names that refer to a phenotype ("phenotype-related" name). When the parent is a gene-related name, all children must be phenotype-related names; conversely, when the parent is a phenotype-related name, all children must be a gene-related name. This naming

Parent (gene-related name): Severe chronic Neutropenia [Testing] [*Reviews*]
  Child (phenotype-related name): Congenital Neutropenia
  Child (phenotype-related name): Cyclic Neutropenia

Figure 1 Alteration in one gene associated with two phenotypes

Parent (phenotype-related name): Hypohidrotic Ectodermal Dysplasia [*Reviews*]
Child (gene-related name): Hypohidrotic Ectodermal Dysplasia, Autosomal [Testing]
Child (gene-related name): Hypohidrotic Ectodermal Dysplasia, X-linked [Testing]

Figure 2 One phenotype associated with alteration in one of the two genes

system allows clinically available testing ("Testing" button) to be associated with gene-related names only. Examples of search results are given in Figures 1 and 2.

5. Cancer risk assessment and management

PDQ Cancer Genetics section (**www.cancer.gov/cancerinfo/pdq/genetics**) of the Cancer Information portion of the National Cancer Institute website provides a Cancer Genetics Overview, a discussion of the Elements of Cancer Genetics Risk Assessment and Counseling, and summaries of evidence-based information about the genetic basis of breast and ovarian cancer, colorectal cancer, medullary thyroid cancer, and prostate cancer.

6. Consumer-health-oriented information

1. The Genetic and Rare Conditions site, University of Kansas Medical Center (**www.kumc.edu/gec/support/**), maintained by Debra Collins, Mississippi. Over 550 pages with links to lay advocacy and support groups, information on over 200 genetic conditions/birth defects for professionals, educators, and individuals, links to sites for children and teens.
2. Family Village: A Global Community of Disability-Related Resources (**www.familyvillage.wisc.edu/index.html**), provides both disease-specific information as well as general information directed at parents of individuals who have disabilities. This site has general resources such as communication, adaptive products and technology, recreational activities, education, worship, and disability-related media and literature.
3. Genetic Home Reference (**http://ghr.nlm.nih.gov**), developed by the National Library of Medicine of the NIH, contains descriptions of ~100 genetic conditions and the genes responsible for those conditions, links to resources and patient support information for those disorders, and general educational materials and a glossary.
4. GeneTests (**www.genetests.org**) provides disease-specific consumer-health-oriented resources accessed within a *GeneReview* or the "Resources" button displayed in a disease search result.
5. Genetic Alliance (**www.geneticalliance.org**), a consumer-health-oriented organization of more than 600 advocacy, research, and health care organizations that maintains a directory of support groups that can be searched by genetic condition, organization, and services offered.

7. Clinical genetics service providers (Table 1)

Table 1 Clinical genetics service providers

Organization	Directory	Search parameters
GeneTests: Clinic Directory **www.genetests.org**	>1000 US genetics clinics	Zip code, state, city, services, specialty clinics
American Board of Genetic Counseling, American Board of Medical Genetics, American College of Medical Genetics, American Society of Human Genetics	Clinical geneticists, laboratory directors, genetic counselors, nurses in genetics, researchers	Alphabetical, geographical

The microdeletion syndromes

Jodi D. Hoffman and Elaine H. Zackai
The Children's Hospital of Philadelphia, Philadelphia, PA, USA

1. Case presentation

A 3-year-old white girl presents to your clinic for evaluation of multiple problems. She recently moved from another state, and her new pediatrician wonders if there might be a genetic etiology for her medical issues.

She was the second child to her 31-year-old gravida 2 para 2 mother after a pregnancy complicated by the finding of an interrupted aortic arch on fetal ultrasound. After the discovery of the cardiac defect, an amniocentesis was performed that showed a normal 46,XX karyotype. The child was born at 38 weeks via spontaneous vaginal delivery at a university hospital with a weight in the 25th percentile and height and head circumference in the 10th percentile. She was stabilized in the NICU prior to surgery. On chest X ray, she was noted to have thymic aplasia. Her cardiac defect was repaired without complication, other than multiple episodes of hypocalcemia, which resolved with medical management. She was discharged at 4 weeks of age. Since her discharge, she has had multiple ear infections, gastroesophageal reflux with weight loss requiring treatment with a proton pump inhibitor, has been noted to have short stature, and has a delayed speech compared to her older sister at similar age. Her parents are slightly concerned about her gross motor milestones and enrolled her in a local early intervention program.

On physical examination, she is noted to be a shy, petite child who does not strongly resemble either parent. She says several words and you note a hypernasal tone to her voice. Her weight is 10th percentile, height just below the 5th percentile, and head is 10th percentile. Her face appears slightly long. Her eyes are deeply set and hooded. Her nose has a bulbous tip. Her ears are slightly low set and the helices are overfolded. She has a chest scar from her cardiac surgery. Her chest and abdominal exam are unremarkable other than the presence of a small umbilical hernia. Her fingers are long-appearing and tapered.

In summary, you have a short 3-year-old female with a history of repaired interrupted aortic arch, resolved hypocalcemia, multiple ear infections, gastroesophageal reflux, delayed hypernasal speech, dysmorphic features, who had a previously normal karyotype. How should you approach this case?

2. Discussion

This child has multiple system involvement (cardiac, endocrine, immunologic, gastrointestinal) and dysmorphia. What should one consider in children who have

differences in several apparently unrelated systems? In taking a birth and pregnancy history, it is important to ask about medication and drug exposures (alcohol, valproate, warfarin, or other teratogens) that could lead to multisystem involvement. If there are no obvious exposures, next it is important to assess whether any in utero infections (CMV, parvovirus, rubella, etc.) could be the etiology of the child's differences. If the infectious work-up is also unrevealing, chromosomal abnormalities should be considered.

The constellation of multiple congenital abnormalities and dysmorphic features that occur together repeatedly in unrelated patients is referred to as a syndrome. Syndromes can be due to a multitude of etiologies including chromosomal deletions, duplications, and rearrangements, uniparental disomy, gene deletions, single gene mutations (autosomal recessive, autosomal dominant, X-linked), triplet repeat expansions, and imprinting.

In the case described above, the child had an amniocentesis in utero due to the finding of a cardiac defect. The karyotype was a normal (46,XX), decreasing the chance that the cause of this child's abnormalities was a large chromosomal deletion, duplication, or rearrangement. Because the study was performed on amniocytes, which cannot be analyzed at as detailed a level as lymphocytes, there is still a small possibility that a cytogenetically detectable abnormality was missed.

In order to understand this child's findings, the next question to ask is: Has this combination of findings ever been seen before? The patient has a cardiac defect, thymic aplasia, and hypocalcemia; cardinal features of classic DiGeorge syndrome (DiGeorge, 1965). A small number of patients were found to have translocations in a common area of the long arm of chromosome 22 (de La Chapelle *et al*., 1981; Kelley *et al*., 1982). Later, 25% of patients were found to have cytogenetically visible interstitial deletions in the 22q11 region.

In 1991, a method now referred to as FISH (fluorescence in situ hybridization) became available to look for noncytogenetically apparent chromosomal changes such as microdeletions (Lichter *et al*., 1991; Trask, 1991). With FISH, a fluorescent probe is specifically designed for a given chromosomal region. The probe is then used to look for the presence or absence of two intact copies of a critical region known to be deleted in those with a syndrome. In 1992, it was found that the vast majority of patients with DiGeorge syndrome who did not have a cytogenetically visible abnormality had a microdeletion of approximately 3 million base pairs on the long arm of chromosome 22 (Driscoll, 1992). Microdeletions are described as "contiguous-gene" deletions (Emanuel, 1988), which may lead to syndromes with multiple systems involvement.

This patient has hypernasal speech and tapered fingers, features described in the velocardial facial syndrome (VCFS) (Shprintzen *et al*., 1978). This syndrome as well as the conotruncal anomaly face syndrome (CFS) and some cases of Opitz G/BBB syndrome were all eventually found to have the same etiology – a microdeletion of chromosome region 22q11.2. Owing to the ability to identify a unifying etiology for these overlapping phenotypes, many people now group DiGeorge syndrome, VCFS, and CFS together as the 22q11.2 deletion syndrome.

Although in 10% of cases the 22q11.2 deletion syndrome is transmitted in a familial fashion, it is most often seen sporadically, with a high prevalence, approximately 1 in 3000 live births. Recently, it has been found that chromosomal

Table 1 Microdeletion syndromes

Syndrome	Deletion	Classic features
DiGeorge/VCFS/CFS	22q11.2	Congenital heart defects, dysmorphic features, immune abnormalities, hypocalcemia, developmental delay
Williams Syndrome	7q11.23	Supravalvular aortic stenosis, hoarse voice, prominent lips, mental retardation, hypercalcemia
Smith Magenis Syndrome	17p11.2	Self destructive behavior, speech delay, mental retardation, brachycephaly, midfacial hypoplasia
Langer–Giedion Syndrome	8q24.11-13	Multiple exostoses, redundant skin, bulbous nose, prominent ears, mental retardation
Prader Willi syndrome	15q11-13	Hypotonia, severe obesity, small hands and feet, mental retardation
Angelman syndrome	15q11-13	Severe mental retardation, absence of speech, paroxysms of laughter, ataxic gait, seizures, characteristic facies
Miller–Dieker Syndrome	17p13.3	Lissencephaly, microcephaly, vertical forehead ridging, mental retardation, initial hypotonia, failure to thrive, seizures
WAGR Syndrome	11p13	Wilms tumor, aniridia, genitourinary abnormalities, mental retardation

regions that are repeatedly deleted in multiple patients are often flanked by low-copy repeats that make the DNA in the area unstable and more susceptible to deletions, duplications, and rearrangements (Emanuel and Shaihk, 2001).

The 22q11.2 syndrome as well as other microdeletion syndromes (Table 1) are most often not visible cytogenetically. As in this case, the signs and symptoms in an individual patient may lead to a specific syndrome diagnosis for which there is now the availability of FISH on a clinical diagnostic basis. These FISH tests must be ordered specifically.

Cancer genetics

Katherine A. Schneider, Kelly J. Branda and Anu B. Chittenden
Dana-Farber Cancer Institute, Boston, MA, USA

Kristen M. Shannon
Massachusetts General Hospital, Boston, MA, USA

1. Introduction

Over the past 10 years, clinical cancer genetics has become established as an important medical specialty that bridges oncology and genetics. This overview article will provide basic information about cancer susceptibility genes, describe features of 12 hereditary cancer syndromes, and detail the main components of cancer genetic counseling sessions.

2. Basic cancer genetics

At a cellular level, the process of growth and division must occur properly in order to maintain a state of balance in the body. The cell cycle is controlled by complex processes and is highly regulated. Underlying the development of all cancers is the accumulation of mutations in the genes that control the cell cycle. While the protein products of thousands of genes play roles in cell cycle control at different times and in different tissues during a person's life, there are three classes of genes that are highly important in the development of cancers. These gene groups are tumor suppressor genes, DNA repair genes, and proto-oncogenes. Germline mutations in any of the genes in these three groups can lead to hereditary susceptibility to cancer. However, it is important to note that hereditary cancer syndromes only account for a small percentage (5–10%) of the 1.3 million cancers that will be diagnosed in the United States this year (American Cancer Society, 2004).

3. Tumor suppressor genes

Tumor suppressor genes serve as the security branch of the cell and are the most common cause of hereditary cancer. The protein products of these genes are

involved in recognizing replication errors, aiding in DNA repair and facilitating cell suicide (apoptosis) if necessary (Fearon, 1998). Since almost all genes are inherited in pairs, most cells have two copies of a necessary tumor suppressor gene in place to provide a backup system if one copy (allele) stops working because of gene mutation.

One of the best-known tumor suppressor genes is the *Rb* gene. After studying children with sporadic and hereditary forms of retinoblastoma (a childhood eye tumor), Dr. Alfred Knudson proposed his now-famous hypothesis regarding the development of cancer (Knudson, 1993). His "two-hit" model states that two mutagenic events are needed, which knock out both copies of the *Rb* susceptibility gene. Individuals with sporadic retinoblastoma develop eye tumors, because two "hits" (mutations in each *Rb* gene) were acquired somatically in a single retinal cell. However, individuals with the hereditary form of retinoblastoma only required one somatic hit to develop a tumor, because their initial hit was an inherited mutation in one copy of the *Rb* gene. This explained why children with an inherited form of retinoblastoma tended to develop bilateral disease at younger than usual ages.

4. DNA repair genes

The second most common type of cancer susceptibility gene is the DNA repair gene. These genes are involved in identifying and correcting mistakes that occur during the replication process. Mutations in DNA repair genes can lead to the accumulation of mutations in other genes involved in cell cycle control, and thereby lead to overgrowth and cancer (Pearson *et al*., 1998). The most common hereditary form of colorectal cancer, termed hereditary nonpolyposis colorectal cancer (HNPCC), is caused by mutations in one of several DNA mismatch repair genes (see Table 1) (Lucci-Cordisco *et al*., 2003).

5. Proto-oncogenes

Although this occurs less commonly, proto-oncogenes can also be involved in inherited susceptibility to cancer. Proto-oncogenes are genes whose protein products typically activate some process in the cell that switches the cell cycle into the "on" position, triggering cellular growth. Inherited mutations in these genes can lead to the inability of a cell to turn off the growth process (Park, 1998). The most well known example of proto-oncogene mutation leading to hereditary susceptibility to cancer is the *RET* proto-oncogene. Germline *RET* mutations lead to one of three endocrine cancer syndromes, all of which involve hereditary susceptibility to medullary thyroid carcinoma (MTC) (Eng, 1999). It is now considered standard-of-care in medicine to test anyone with a diagnosis of MTC for mutations in the *RET* proto-oncogene. If a mutation is identified, predictive genetic testing of family members can reveal which family members are at risk to develop MTC. Early screening and preventative removal of the thyroid can be life-saving in this situation (Eng, 1999).

Table 1 Clinical features and associated genes of selected hereditary cancer syndromes

Syndrome	Gene (chromosomal location)	Gene type	Inheritance pattern	Clinical features
Cowden Syndrome (CS)	*PTEN* (10q23)	Tumor suppressor	AD	Cancers: thyroid, breast, endometrial, renal cell, melanoma, glioblastoma Other: trichilemmomas, acral keratoses, papillomatous papules, mucosal lesions, macrocephaly, Lhermittte–Duclos disease, thyroid disease, mental retardation, gastrointestinal hamartomas, fibrocystic breasts, lipomas or fibromas, genitourinary tumors, genitourinary malformations
Familial Adenomatous Polyposis (FAP)	*APC* (5q21)	Tumor Suppressor	AD	Cancers: colon, thyroid, ampulla of Vater, bile duct, small intestine, hepatoblastoma, brain tumors Other: desmoid tumors, dental abnormalities, CHRPE, osteomas
Familial Medullary Thyroid Cancer (FMTC)	*RET* (10q11.2)	Proto-oncogene	AD	Cancers: medullary thyroid cancer Other: none
Familial Melanoma (FAMM)	*CMM1* (1p36) *CDKN2A/TP16* (9p21) *CDK4* (12q14)	Tumor suppressor	AD	Cancers: melanoma, astrocytomas, pancreas
Familial Retinoblastoma (RB)	*RB1* (13q14.1)	Tumor suppressor	AD	Cancers: retinoblastoma, osteosarcoma, Ewing sarcoma, leukemia, lymphoma, melanoma, lung cancer, bladder cancer Other: short stature, microcephaly, mental retardation, genital malformations, ear abnormalities
Hereditary Breast/Ovarian Cancer (HBOC)	*BRCA1* (17q21) *BRCA2* (13q12)	Tumor suppressor	AD	Cancers: female breast, male breast, ovary, pancreas, prostate
Hereditary Nonpolyposis Colorectal Cancer (HNPCC)	*MLH1* (3p21.3) *MSH2* (2p22-p21) *MSH6* (2p16) *PMS1* (2q31) *PMS2* (7p22)	Mismatch repair	AD	Cancers: colon, endometrial, stomach, small intestine, ureter, kidney, brain tumors
Li Fraumeni Syndrome (LFS)	*TP53* (17p13.1)	Tumor suppressor	AD	Cancers: osteosarcomas, soft tissue sarcomas, breast cancer, brain tumors, adrenocortical carcinomas, acute leukemias, stomach, colon, lung, nueroblastomas, melanoma

(*continued overleaf*)

Table 1 (*continued*)

Syndrome	Gene (chromosomal location)	Gene type	Inheritance pattern	Clinical features
Multiple Endocrine Neoplasia, type 2A (MEN2A)	*RET* (10q11.2)	Proto-oncogene	AD	Cancers: medullary thyroid Other: pheochromocytomas, parathyroid tumors
Multiple Endocrine Neoplasia, type 2B (MEN2B)	*RET* (10q11.2)	Proto-oncogene	AD	Cancers: medullary thyroid cancer Other: pheochromocytomas, parathyroid tumors, developmental delay, enlarged lips, mucosal neuromas, ganglioneuromatosis of the intestine, Marfanoid habitus
Von Hippel Lindau Disease (VHL)	*VHL* (3p25)	Tumor suppressor	AD	Cancer: renal cell (clear cell type) Other: retinal angiomas, hemangioblastomas of cerebellum and spine, cysts and adenomas of kidney and pancreas, pheochromocytomas
Xeroderma Pigmentosum (XP)	*XPA* (9q34.1) *XPB* (2q21) *XPC* (3p25.1) *XPD* (19q13.2) *XPE* (11p12-p11) *XPF* (16p13.2-p13.1) *XPG* (13q32-q33)		AR	Cancers: basal cell and squamous cell, melanoma, sarcomas, ocular melanoma, brain tumors, lung, gastric, leukemia Other: mental subnormality, microcephaly, sensorineural deafness, hyporeflexia or areflexia, spacitity/ataxia, abnormal EEG

6. Hereditary cancer syndromes

Over 200 cancer syndromes have been identified, but most are exceedingly rare. Table 1 lists the major clinical features and underlying genes for 12 hereditary cancer syndromes.

Two of the best-defined inherited cancer syndromes are hereditary breast and ovarian cancer syndrome and hereditary nonpolyposis colorectal cancer. These two syndromes are detailed below.

6.1. Hereditary breast and ovarian cancer syndrome

The majority of cases of hereditary breast and ovarian cancer syndrome (HBOCS) are caused by germline mutations in the *BRCA1* or *BRCA2* gene. These genes are inherited in an autosomal dominant manner, meaning that they can be inherited from the maternal or paternal lineage and that they are passed on to daughters and sons with equal frequency. The incidence of inherited *BRCA1* and *BRCA2* mutations in the general population is estimated to be 1/500 to 1/1000 (Szabo and King, 1997). Founder mutations have been identified in several ethnic groups at greater frequencies. For example, 1 of 40 people of Ashkenazi Jewish ancestry will have one of three founder mutations: 187delAG and 5385 insC mutations in *BRCA1* and 6174delT mutation in *BRCA2* (Struewing *et al*., 1997).

Women with HBOCS have a 50–85% lifetime risk of breast cancer. The risk of developing a second primary cancer in the contralateral breast is thought to be 50–60%. In general, breast cancers due to *BRCA2* mutations occur at older ages than those associated with *BRCA1* mutations. The risk of ovarian cancer is 20–40% for women with *BRCA1* mutations and 15–20% for women with *BRCA2* mutations. Risks of peritoneal cancer and fallopian tube cancer are also increased. Breast cancer risk in men is 6–10% with *BRCA2* mutations and is also thought to be increased, but less so, for men with *BRCA1* mutations. Men with HBOCS also have increased risks for prostate cancer. Individuals with *BRCA2* mutations may also have small, increased risks of melanoma (of the skin and eye) and cancers of the pancreas, bile duct, and stomach (Petrucelli *et al*., 2004).

6.2. Hereditary nonpolyposis colon cancer

Hereditary nonpolyposis colon cancer (HNPCC) is an inherited cancer syndrome that accounts for about 5% of colon cancer diagnoses (Offit, 1998). People with HNPCC have up to an 80% risk of developing colorectal cancer over the course of their lifetime, although this risk is largely preventable with routine screening. These tumors often arise in the right-sided region of the colon, and are typically derived from an adenomatous polyp, although frank polyposis is absent. Women with HNPCC have up to a 40% risk of endometrial (uterine) cancer and a 10–12% risk of ovarian cancer. Other HNPCC malignancies include cancers of the stomach, pancreas, and small intestine, as well as transitional cell cancers of the kidney and bladder. Additional features are present in subtypes of HNPCC. These include sebaceous gland tumors and skin keratocanthomas found in Muir–Torre syndrome and brain tumors (primarily glioblastomas) seen in Turcot syndrome (Kohlmann and Gruber, 2004).

HNPCC is clinically diagnosed using Amsterdam I or II criteria. Amsterdam I criteria states that families must have at least three cases of colorectal cancer in at least two successive generations, two of these cases must occur in first-degree relatives and one of the colon cancers must have been diagnosed at age 50 or younger (Vasen *et al*., 1991). Amsterdam II criteria broadens the definition to include other HNPCC malignancies (Vasen *et al*., 1999).

HNPCC can be caused by germline mutations in several different mismatch repair genes, but about 40–80% of families that meet classic Amsterdam I criteria will have a detectable *MLH1* or *MSH2* mutation (Syngal *et al*., 2000). It is thought that families with variant forms of HNPCC may have specific gene mutations leading to these phenotypes. For example, several families with Turcot syndrome have specific *PMS2* mutations (Hamilton *et al*., 1995).

Nearly 90% of the colon tumors that develop in individuals with HNPCC show a feature known as microsatellite instability (MSI). In contrast, MSI is only seen in about 15% of sporadic colon tumors (Wahlberg *et al*., 2002). Microsatellites are a family of repetitive DNA, which is typically repeated a fixed number of times at any given chromosomal locus. The difference in MSI rates allows this to be a useful screening test to determine the likelihood that a family has HNPCC. The Bethesda criteria can be useful in determining whether individuals should undergo MSI tumor analysis (Rodriguez-Bigas *et al*., 1997; Boland *et al*., 1998).

7. Cancer genetic counseling

Cancer genetic counseling is a communication process concerning an individual's risks of developing specific inherited forms of cancer. This risk may be higher than or similar to the general population risks of cancer. Counseling can, but does not always, lead to genetic testing. For additional information about genetic counseling services and providers, please refer to Article 75, **Changing paradigms of genetic counseling**, Volume 2.

8. Genetic counseling sessions

Patients are often referred to a cancer genetic counselor by their oncologists or other health care providers. However, an increasing number of patients are self-referred. Genetic counseling sessions involve collecting the family history, providing an assessment of the risk of certain cancers and the likelihood of having an inherited susceptibility to cancer, describing options for medical follow-up, and arranging genetic tests as appropriate (Schneider, 2002).

8.1. Collecting family histories

The first and most important step in assessing a patient's hereditary cancer risk is the collection of a careful and detailed family history. Pedigrees typically span 3–4 generations and include both sides of the family. For each affected member of the family, information is obtained about the cancer diagnosis including the exact location of the tumor, the stage at diagnosis and how the cancer was treated. Precancerous conditions (e.g., colonic polyps) are also ascertained, as should benign, but possibly related, conditions (e.g., nevi). Since the risk assessment and subsequent recommendations are based on the pattern of cancerous and

precancerous tumors in the family, it is important that the information be accurate. Thus, counselors typically request written documentation of the relatives' cancer diagnoses.

8.2. Providing risk assessments and follow-up options

Families can be categorized as having a high, moderate, or low likelihood of having a hereditary predisposition to cancer. High-risk families have patterns of cancer that are suggestive of a hereditary cancer syndrome and affected members are assumed to carry an inherited gene mutation. In this instance, the patient's cancer risks can be estimated by his/her position in the pedigree, current age, absence or presence of associated features, and the age-specific penetrance of the genes in question. At-risk individuals are generally recommended to undergo additional cancer surveillance at more frequent intervals than in the general population. They may also have the option of risk-reducing strategies, such as chemoprevention or prophylactic surgery.

In moderate-risk families, there may be a few features suggestive of an inherited cancer syndrome, but not enough to make a diagnosis. Estimating a patient's cancer risk in this instance may involve the use of empiric data or a range of risk. Recommendation about medical follow-up may be based on the specific cancer(s) seen in the family rather than all of the malignancies associated with the syndrome in question.

Members of low-risk families can be reassured about the low likelihood of an inherited risk factor in the family and can be given standard information about cancer surveillance and risk avoidance.

8.3. Arranging genetic testing

Genetic testing is currently available for over 50 hereditary cancer syndromes (**www.genetests.org**). Discussions about genetic testing include testing eligibility (including the person in the family who should be tested initially), possible test results, limitations of test results, implications of a positive test result for the patient and other family members, pros and cons of testing, and logistics. Logistical issues include whether testing will be done in a clinical or research laboratory, the cost of the analysis, the number of counseling visits in the testing program, when results are likely to become available, how results will be given, and whether results will be placed in the patient's medical record. Special counseling issues include patient concerns about discrimination and stigma, emotional distress engendered by the family's experiences with cancer or test results, strain on family relationships, and ethical dilemmas that range from decisions about duty to warn other family members about cancer risks to balancing family rights.

C. Sue Richards
Oregon Health & Science University, Portland, OR, USA

1. Case studies

1.1. Case 1

DK (III-1), a 17-year-old Caucasian male, presented to his GP with irregular bowel and bleeding. DK was referred for evaluation to a GI specialist because of a family history of colon cancer in three generations (Figure 1). GI evaluation showed the presence of thousands of adenomatous and hyperplastic polyps. Subsequent eye examination by an ophthalmologist with a genetics subspecialty showed congenital hypertrophy of the retinal pigment epithelium (CHRPE). On the basis of the family history and clinical presentation, a diagnosis of familial adenomatous polyposis (FAP) was given and genetic testing was ordered to confirm the diagnosis.

1.2. Case 2

GS (II-2), a 47-year-old Caucasian male, presented to his GP with inflammatory bowel disease. GS was referred for evaluation to a GI specialist for surveillance colonoscopy due to his increased risk for colorectal cancer (CRC) associated with these conditions and because of his family history of colon cancer (Figure 2). GI evaluation showed the presence of approximately 100 adenomatous polyps. GS was given a probable diagnosis of Attenuated FAP (AFAP) and referred for genetic counseling based on his family history. Molecular testing for *APC* gene mutations was recommended to confirm his diagnosis and to characterize the mutation.

1.3. Case 3

NJ (III-1), a newborn male of mixed Caucasian/Hispanic heritage, presented to his pediatrician with voluminous osteoma in the frontal areas associated with diffuse subcutaneous lipomas. Clinical examination revealed skin cysts and diffuse

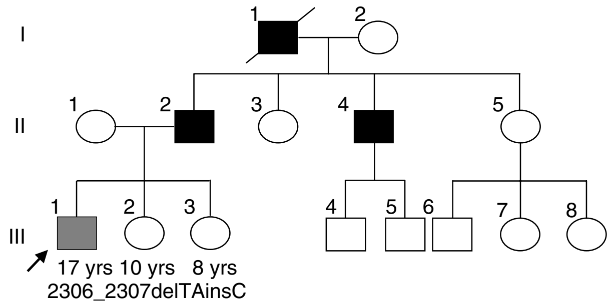

Figure 1 Pedigree for case 1. The 2306_2307delTAinsC mutation was identified in the proband. Black symbols = CRC; gray symbol = symptomatic proband

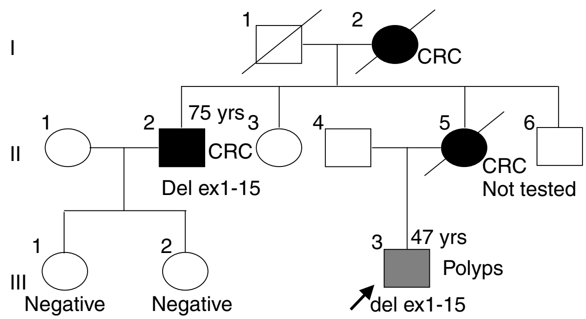

Figure 2 Pedigree for case 2, an AFAP family. A deletion of one copy of exons 1-15 was identified in the proband and his affected maternal uncle. Black symbols = CRC; gray symbol = symptomatic proband

increased pigmentation of the skin. NJ was referred to a GI specialist for further evaluation with a possible diagnosis of Gardner syndrome. GI evaluation revealed the presence of a carpet of colonic polyps. NJ has no family history of FAP (Figure 3). Molecular testing for *APC* gene mutations was ordered to confirm his diagnosis.

2. Background

Colorectal cancer (CRC) is the third most commonly diagnosed cancer and cause of cancer deaths in the United States, with an estimated 147 500 newly diagnosed cases and 57 100 deaths in 2003 (Lynch and de la Chapelle, 2003; *see* Article 65, **Complexity of cancer as a genetic disease**, Volume 2). Most of the CRC is sporadic, but some of the genes responsible for the hereditary CRC syndromes have been identified, and routine genetic testing is available. The most prevalent of inherited CRCs include hereditary nonpolyposis colon cancer (HNPCC) and familial adenomatous polyposis (FAP), and more recently MYH associated polyposis (MAP) (Sieber *et al*., 2003). Individuals who inherit a germline mutation in one of the mismatch repair genes have an approximately 80% lifetime risk of developing

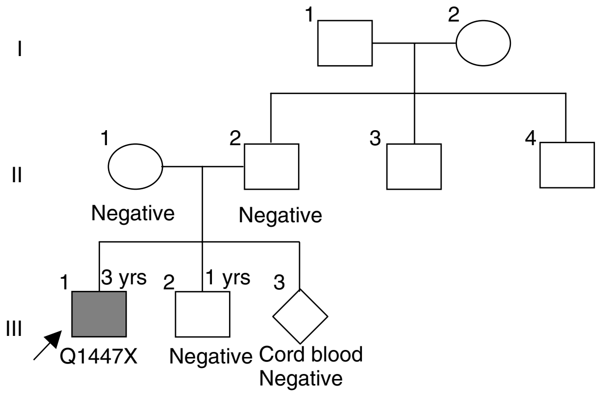

Figure 3 Pedigree for case 3. The novel Q1447X mutation was identified in this sporadic case of Gardner syndrome. Both parents and two unaffected siblings tested negative. Solid symbol = affected

CRC (Lynch and de la Chapelle, 2003). That risk is even greater (>95%) for individuals who inherit an *APC* mutation resulting in the FAP phenotype. For these families, screening surveillance is more intense and begins at an earlier age. Surveillance includes annual colonoscopy from adolescence, and if polyps are detected, prophylactic colectomy to eliminate the risk of CRC. If untreated, the majority of classical FAP patients will develop CRC, generally by the fourth decade of life.

FAP is inherited as an autosomal dominant and accounts for up to 1% of all colorectal cancers (Cama *et al*., 1997). The incidence of FAP is estimated at approximately 1 in 5000 individuals in the United States. Classic FAP is characterized by the presence of hundreds to thousands of adenomatous colorectal polyps, which usually first appear in the distal colon during adolescence and progress to CRC if prophylactic total colectomy is not performed. Extra-colonic features may include gastric polyps, osteomas, congenital hypertrophy of the retinal pigment epithelium (CHRPE), soft-tissue tumors, thyroid carcinoma, and hepatoblastoma. Other known variants of FAP include attenuated FAP (AFAP) (Friedl *et al*., 1996), which is characterized by late onset and lesser number of polyps, Gardner syndrome, which typically is associated with a number of extra-colonic features, and Turcot syndrome associated with brain tumors (medulloblastoma), in addition to colon polyps and CRC.

2.1. *APC gene*

In 1991, the understanding of the molecular pathogenesis of CRC was profoundly altered by the identification of the causative gene for FAP, the adenomatous polyposis coli *(APC)* tumor suppressor gene, located on chromosome 5q21-22 (Fearnhead *et al*., 2001; Bodmer *et al*., 1987). The *APC* gene consists of 8535 base pairs, encoding a 2843 amino acid protein (Figure 4) (Fearnhead *et al*., 2001). While the gene is composed of 15 exons, exon 15 accounts for >75% (6.5 kb) of the

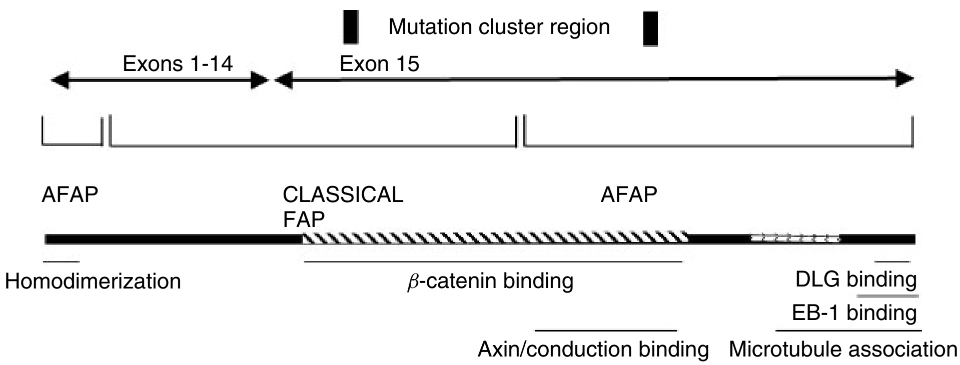

Figure 4 A schematic representation of the *APC* gene: exons 1-14 and exon 15 are shown with mutation cluster region, functional domains, and disease phenotype for each region. Functional domains are shown under the bar: homodimerization, β- catenin binding, DLG binding domain (lethal (1) discs large-1), EB-1 protein binding domain, axin/conduction binding domain, and microtubule association region

coding sequence and contains the vast majority of mutations, which are truncating mutations (~90%) and include small deletions, small insertions, and nonsense mutations. The remainder consists of missense mutations (~4%) and gross alterations (~5%) (Fearnhead *et al*., 2001). The mutation spectrum is scattered across the gene with a number of recurrent mutations, particularly codon 1309 and 1068 in exon 15. Exon 15 (~1200–1400) contains a mutation cluster region (MCR) in which sporadic mutations occurring in CRC tumors as second events in Knudson's hypothesis are often found.

The majority of *APC* mutations in FAP are found to cause premature truncation of the protein product, which results in abnormal protein function. These germline truncating mutations in *APC* are detectable in over 80% of patients with classic FAP. Most commonly, the protein truncation test (PTT) (van der Luijt *et al*., 1994) has been used for the detection of truncating mutations in the *APC* gene, but this technique depends on the availability of cDNA, and accuracy of mutation detection is based on the position and type of mutation. Recently, several new techniques have been described and include mutation scanning using conformational sequencing gel electrophoresis (CSGE) (Arancha *et al*., 2002) and denaturing high-performance liquid chromatography (dHPLC) (Wu *et al*., 2001), followed by sequencing to characterize the mutation. More recent studies have also demonstrated the presence of large rearrangements/deletions or mutations within the *APC* promoter that affect gene expression. These large gene rearrangements may contribute to the remaining 20% of *APC* mutations (Su *et al*., 2000).

2.2. *APC gene function*

The *APC* gene product functions as a tumor suppressor with a gatekeeper role at the level of initiation of tumorigenesis (Munemitsu *et al*., 1995). The interactions of the various domains of the *APC* gene product have led to a greater understanding of the many roles for this protein. Structurally, the APC protein can be divided (from

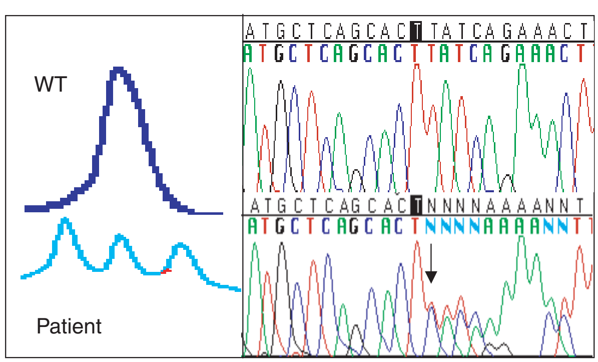
amino to carboxyl terminus) into the following domains: a homodimeric-binding region; β-catenin binding region; axin-binding region; and microtubule-binding region (Figure 4). Perhaps the most important role for the APC protein is a negative regulator in the wnt-signaling pathway. In this role, APC binds β-catenin and also binds to axin, which increases the binding to β-catenin, and facilitates the phosphorylation of β-catenin by GSK-3β, leading to the degradation of β-catenin in the proteosome (Rubinfeld *et al*., 1996). If β-catenin is not regulated by APC, its concentration increases within the cell and it diffuses into the nucleus where it interacts with Tcf and other transcription factors to increase the expression of downstream genes, including myc and cyclin D, thus leading to unregulated growth control. Thus, mutations occurring in the β-catenin-binding domain generally lead to more classical phenotypes.

2.3. *Treatment*

After the diagnosis of FAP is made, if the patient is left untreated, the risk of colon cancer is near 100%, and median life expectancy is approximately 42 years. Disease management consists of lifetime endoscopic surveillance, initial colon resection followed by complete resection, if required, and may involve repeated surgeries. Given the serious consequences of FAP in terms of cancer risk and the need for repeated major surgical interventions, there has been interest in developing a systemic treatment with low toxicity that could reduce polyp burden as an adjunct to surgery. One potential pharmacologic target in impeding growth of adenomatous tissue is the cyclo-oxygenase (COX) enzyme (Phillips *et al*., 2002). The recent development of selective COX-2 inhibitors has provided the opportunity to more safely test the hypothesis that selective inhibition of COX-2 might be useful in the prevention or treatment of adenomatous polyps, and clinical trials are under way.

2.4. *Genetic counseling*

Genetic counseling is strongly recommended for FAP families. Unlike other genetic disorders with adult onset, FAP in the classical form is manifested in children. Thus, it is important to counsel parents about the clinical symptoms, course of disease, surveillance measures, and treatment options, as well as provide an avenue for genetic testing. Genetic testing of the proband in the family is important first to identify the *APC* mutation segregating within the family and to confirm the diagnosis. Among confirmed gene mutation carriers, preventive health options include frequent screening, and for those individuals who develop many colorectal polyps, surgical removal of polyps via colectomy. Identification of the mutation in the proband then allows genetic testing for at-risk family members. In such cases, there are two possible outcomes. If the at-risk family member is found to carry the same *APC* gene mutation as in the proband and is currently asymptomatic, enrollment in drug trials aimed at delay or prevention of tumor development may be an option along with frequent surveillance monitoring. For those family members



who receive genetic testing and are found to be negative for the familial mutation, frequent, costly and unpleasant colonoscopies can be avoided. It is important to remember that negative results do not eliminate the risk of CRC; thus, the same general population guidelines for colon screening at a later age would apply.

3. Case study approaches

3.1. Approach to case 1

A blood specimen from DK was sent to the clinical laboratory for *APC* mutation analysis. dHPLC analysis was performed and a mutation was identified in exon 15 in one copy of the *APC* gene (Figure 5). Sequence analysis revealed a 2-bp deletion and 1-bp insertion mutation at nucleotide position 2306_2307delTAinsC (codon 769). This indel mutation results in a frameshift and a stop codon at nucleotide 2326 (codon 776), producing a truncated protein. This mutation has not been previously reported for the *APC* gene in the HGMD (Human Genome Mutation Database), although it is interpreted as a disease-causing mutation. This mutation is predicted to act as a dominant negative mutation, by which, in its presence, the abnormal product from the allele inactivates the product of the normal allele. This mutation lies within the β-catenin binding domain, and thus is predicted to be important for normal function of the APC protein. On the basis of the results of the molecular testing in DK, his diagnosis is confirmed, and testing is available for at-risk family members.

Genetic counseling is strongly encouraged for this family. DK (III-1) has a strong paternal family history of CRC, with two at-risk siblings (III-2 and III-3) and two at-risk paternal first cousins (III-4 and III-5). Genetic counseling issues should be discussed with DK and his family, including the implications of his mutation-positive status for his health care and for other family members, with a

(a) (b)

Figure 5 (a) dHPLC profile for case 1. A dHPLC profile showing the patient (lower) has a different profile from the wild type (upper). (b) Sequence analysis was performed to characterize the 2306_2307delTAinsC mutation (lower) in comparison to wild-type sequence (upper)

recommendation for molecular testing of the affected parent for mutation confirmation. The family should be advised that presymptomatic testing is available for at-risk family members and that additional genetic testing will target the familial mutation identified in DK. The family should also be informed that prenatal testing is available for future pregnancies of mutation carriers. The medical implications discussed with this family should include virtual certainty of development of colorectal cancer for mutation-positive carriers, necessity of continued screening, and options for surgical intervention. The risk for each successive generation based on inheritance of an autosomal dominant disorder should be presented to the family, along with options for genetic testing.

3.2. Approach to case 2

A blood specimen from GS (II-3) was sent to the clinical laboratory for *APC* mutation analysis. After full sequence analysis of the coding region of *APC*, no mutation was detected. However, GS was found to be homozygous for the eight common single nucleotide polymorphisms (SNPs) in the *APC* gene, suggesting a large gene deletion on one allele. Additional testing was performed for gross gene alterations using a real-time quantitative PCR-based assay, and a deletion of the entire *APC* gene was detected (Figure 6a). Confirmation of this finding was done using multiplex ligation probe amplification (MLPA) (Bunyan *et al*., 2004) (Figure 6b) and fluorescence in situ hybridization (FISH) (Rogan *et al*., 2001) analysis (Figure 6c). This exon 1-15 deletion mutation is expected to result in haploinsufficiency of the APC protein, resulting in inefficient downregulation of β-catenin. Thus, these molecular results confirm the diagnosis of AFAP for this patient and allow testing for at-risk family members.

GS has a family history of CRC (Figure 2) with his mother (II-5), maternal grandmother (I-2), and maternal uncle (II-2) affected with CRC. Subsequent targeted genetic testing for the familial *APC* mutation was performed on the affected 75-year-old maternal uncle, identifying the same exon 1-15 deletion mutation and confirming these results. Subsequent genetic testing performed on at-risk individuals (III-1 and III-2) produced negative results. These findings indicate that III-1 and III-2 are at no greater risk for developing CRC than the general population and thus do not require the frequent monitoring by colonoscopy as do mutation-positive carriers.

3.3. Approach to case 3

NJ's (III-1) blood sample was sent to the clinical laboratory for mutation analysis of the *APC* gene. dHPLC and sequencing identified a mutation in exon 15 in one copy of the *APC* gene (Figure 7). A nonsense mutation was detected at nucleotide position 4339C > T, leading to a change of glutamic acid to a stop at codon 1447 (Q1447X) and producing a truncated protein. This novel mutation has not previously been reported in the HGMD, although it is the type expected to cause FAP.

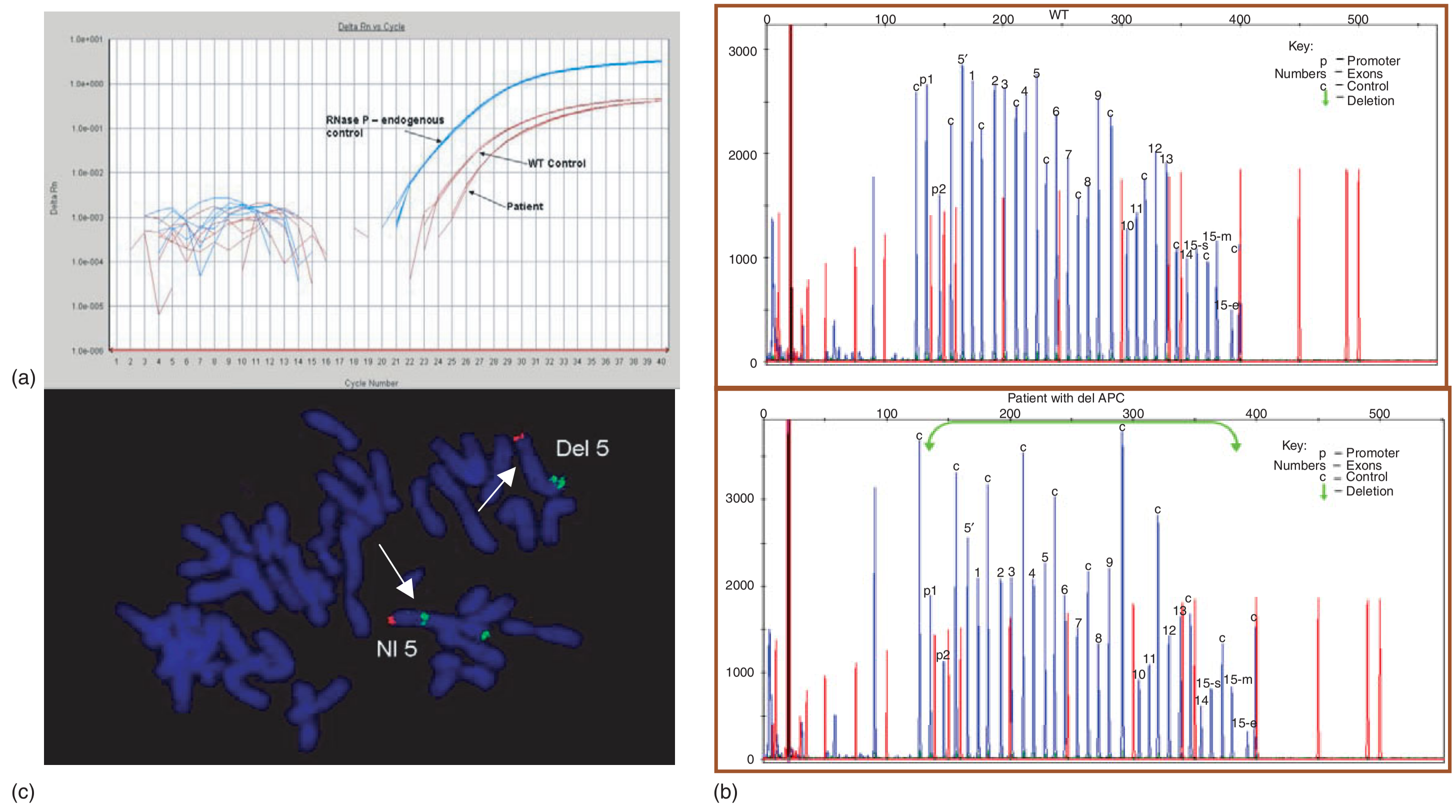


Figure 6 (a) Real-time PCR analysis for the detection of suspected deletions in case 2. Patient sample shows a large deletion spanning the entire coding region of the *APC* gene. The shift showing a difference between the wild-type product and that of the patient indicates that the patient sample has a deletion in the region spanning the exon. (b) MLPA confirmed that the patient has the entire *APC* gene deleted on one allele. The height of the numbered peaks corresponding to each exon is compared to that of the control peaks (c) and the wild-type profile (top panel) is compared with the patient (lower). (c) Confirmation of the gene deletion using FISH. FISH was performed using a biotin labeled BAC RP11-107C15 containing the *APC* gene as a probe (green signal). The 5p telomere (green signals) and the 5q telomere (red signals) were used as control probes. Note that the arrow points to *APC* gene, which is missing in the upper portion of the figure

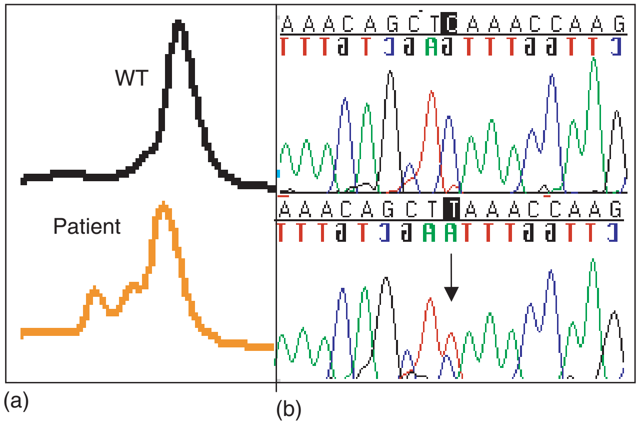

Figure 7 (a) dHPLC and sequence analysis for case 3. The dHPLC profile shows the patient (lower panel) has a different profile from that of the wild-type sample (upper panel). (b) Sequence analysis was performed to characterize the Q1447X mutation. The patient sequence (lower panel) is compared to wild-type sequence (upper panel)

On the basis of the results of the molecular testing for NJ, genetic counseling was strongly recommended. NJ has no family history of Gardner syndrome, and his mother is pregnant (Figure 3). Both parents were tested and were found to be negative for the Q1447X mutation, indicating that their blood cells do not carry the Q1447X mutation detected in their son. However, these results do not rule out the possibility for gonadal mosaicism as the de novo event. Approximately 25% of germline *APC* mutations are de novo events arising either in the germline of the affected offspring or somatically in the germ cells of the parent. Clinical laboratory testing does not distinguish between these two possibilities. Genetic counseling issues were discussed with NJ's family, including the possibility of gonadal mosaicism and the implications for the current and future pregnancies. A sibling (III-2) and the fetus of the current pregnancy (III-3) were subsequently examined to ascertain their carrier status by targeted mutation analysis for the familial mutation, and both were found to be negative. The parents were informed about the recommended surveillance regimen, the availability of COX-2 inhibitors pediatric clinical trials, treatment options, and the expected clinical progression of disease for their affected child. They were reassured that their other two children were at a decreased risk due to their negative test results and would not require frequent lifetime screening procedures.

Introductory Review

Gene therapy I: principles and clinical applications

J. Wesley Ulm
Harvard Medical School, Brookline, MA, USA

1. Introduction

Gene therapy is a novel pharmacological approach in which the drug is supplied in the form of a nucleic acid – DNA, RNA, or some modification or combination thereof. The origin of gene therapy lies in the watershed advancements of two fields, particularly in the 1970s and 1980s: recombinant DNA technology, which enables the precise manipulation and amplification of defined DNA segments and virology, in which progress in the basic science of viral life cycles and replication has allowed for the exploitation of viral particles as vectors to ferry therapeutic DNA or RNA into cells. Although many obstacles remain to be overcome before gene therapy can enter the mainstream of treatment and prevention of human disease, the technology holds great promise. Effective and safe gene therapy would bring pharmacology to the core of the central dogma in biology, treating disease at the level of the purine and pyrimidine nucleic acid polymers that control the fundamental processes of normal physiology and pathophysiology.

2. Why gene therapy?

From a pharmacological perspective, gene therapy presents an attractive option since its very nature is conducive to a high therapeutic index, at least at the cellular level. A DNA or RNA sequence prefabricated to target a particular disease locus constitutes, in principle, a highly specific and minimally toxic therapeutic (as discussed below, the viral vectors currently used in most gene therapy protocols unfortunately introduce a degree of nonspecificity and toxicity, often in the form of an immune response). Gene therapy also affords the prospect of long-term effectiveness from a small number of interventions, enabling physicians to treat efficiently many classes of disease that would otherwise be recalcitrant to therapy. Heritable loss-of-function genetic diseases such as cystic fibrosis (CF), the hemophilias, sickle-cell anemia, Duchenne muscular dystrophy, and many others represent the classic targets for gene therapy. A gene therapy protocol providing a stable supply of a missing or damaged protein could obviate the need for the chronic, expensive,

and often only partially effective (e.g., hemophilia, the thalassemias) or palliative (e.g., CF, Tay–Sachs disease, Lesch–Nyhan syndrome) treatments that currently exist. In practice, most protocols recently have focused on cancer, heart failure, and angiogenesis, but recessive genetic diseases still represent the canonical target for which gene therapy was originally conceived.

Finally, gene therapy provides a flexible treatment strategy that could be readily adapted to treat novel pathogens and even overcome resistance. Modern medicine, particularly the antimicrobial and anticancer chemotherapeutic drugs introduced in the wake of World War II, has in some respects become a victim of its own success. Such treatment regimens frequently become case studies in cellular microevolution, as the drugs are ultimately selected for targets that are resistant to their mode of action. This challenge has repeatedly foiled many a promising new cancer treatment: a novel drug seems to clear the tumor from a patient's body, only to have a relapse occur months or years later because of the outgrowth of a few cells with a multidrug-resistance membrane pump or an overamplified or mutated protein target. It is here that a gene therapy scheme could demonstrate great benefit. If a drug target (e.g., a pathogenic bacterium or a relapsing tumor) were to acquire a resistance phenotype against a small molecule therapeutic, it would be a long and time-consuming process to generate and screen new small molecules to adapt to the change, even with modern improvements in computer modeling and robotic technologies. A linear DNA sequence, in contrast, could be rapidly and reliably altered to target the new gain-of-resistance mutation. In a novel paradigm of treatment, gene therapy remedies could be tailored to each patient and dynamically adapted to respond to resistance as it arises.

3. Prospects for clinical application

As will be discussed in specific cases below, many gene therapy modalities have made the leap from bench to bedside in the form of clinical trials. While gene-replacement strategies represent the canonical application of gene therapy, in practice, most trials have focused on cancer and blood vessel disease, two areas with a large pool of patients and a high index of clinical applicability for the therapeutic vectors of interest. Although many novel modalities have attracted substantial interest and shown promise in the laboratory, to date most clinical trials with gene therapy have had disappointing results. The first such clinical trial was undertaken by French Anderson and colleagues in the early 1990s to treat pediatric patients with adenosine deaminase (ADA) deficiency, a disorder that prevents proper development of lymphocytes and renders patients immunodeficient. These studies involved the ex vivo introduction of retroviral vectors (discussed below) bearing an ADA expression cassette into hematopoietic cells, followed by their injection into patients' bone marrow. The results of the work were confounded, however, by the concurrent administration to the trial participants of PEG-ADA, a traditional pharmaceutical regimen for ADA patients that has made the interpretation of the trial data rather difficult.

Hundreds of other trials have since been launched, occasionally with hints of efficacy but in general failing to exceed the threshold that would allow gene therapies to surpass more established pharmaceuticals in clinical practice. The one exception to this in recent years has been the work of Alain Fischer and colleagues in France, who in 2000 and 2002 reported the successful use of a retroviral-based modality to reconstitute the immune systems of patients suffering from an X-linked congenital form of severe combined immune deficiency (discussed below). The results of the trial have been partly marred by the subsequent development of a T-cell leukemia (albeit one highly amenable to chemotherapeutic treatment) in 3 out of the 10 patients in the study; yet, the French trial nonetheless represents the first demonstration of a sustainable, long-term correction of an inherited disorder using a gene therapy approach (see Cavazzana-Calvo *et al*., 2000; Hacein-Bey-Abina *et al*., 2002).

The difficulties and frustrations encountered in most clinical trials so far should not lead to the premature conclusion that gene therapy is unworkable in a clinical setting. Most such trials encounter the same subset of obstacles – usually related to vector delivery, efficiency of transduction and intracellular expression, and long-term maintenance of the transgene (see review by Mulligan, 1993) – for which greater understanding is obtained with each new attempt. The benchtop studies and clinical trials cross-pollinate each other, since the basic science investigations are used to design the initial therapeutic protocols and, in turn, themselves benefit from the experience and knowledge gleaned from the trials. The work of Fischer and colleagues in France in particular constitutes a watershed not only for inherited diseases but also for the field in general, and demonstrates that gene therapy can indeed provide a viable approach to treat patients for whom no other effective treatment is available. Furthermore, strategies like oncolytic viruses and neoplastic apoptosis induction offer the prospect of anticancer treatments far more selective than most available today, while improved applications of RNA interference techniques especially suggest a practical methodology to design new and effective drugs far more rapidly than is required for most small molecules. Gene therapy is thus built on well-established phenomena and proven technologies that can potentially fine-tune medicine in a manner that is elusive for most pharmacological modalities, and the early hurdles of clinical trials constitute the difficult yet inevitable learning curve that must be surmounted to attain clinical practicality.

The next sections will discuss the various gene therapy strategies, organized according to classes of disease targets, requirements for safe and effective treatment, and viral gene therapy vectors currently under development.

4. Classes of disease targets

To which areas of human disease could a viable gene therapy protocol be applied to the greatest advantage? While this answer can only be conjectured at the present, current proposals for clinical trials and topic reviews tend to focus on the following (summarized in Table 1).

Table 1 Examples of diseases for which gene therapy has been used or is being considered

Class	Exemplary diseases	Mutated gene product	Result
Mendelian, homozygous recessive loss-of-function	Cystic fibrosis	CFTR, a cell-surface chloride channel	Deficient luminal water transport, salty sweat, pulmonary infections, male sterility, exocrine pancreas insufficiency, intestinal obstruction
	Familial hyper-cholesterolemia	Low-density lipoprotein (LDL) receptor	Extremely elevated plasma LDL, cholesterol, and triglycerides; xanthomas, xanthelasma; angina, early-onset acute myocardial infarction
	Tay–Sachs disease	Hexosaminidase A	Accretion of ganglioside GM2 in CNS neurons; apathy, retardation, blindness, convulsions, paralysis, macular degeneration, death by age 3
Protein aggregation	Alzheimer's disease	*Tau* protein, amyloid precursor protein (APP)	Anterograde and retrograde amnesia; damage to cholinergic neurons in frontal and temporal lobes (especially hippocampus and amygdala)
Neoplastic	Malignant melanoma	B-Raf, cyclin dependent kinases and cdk inhibitors	Development of dysplastic cutaneous nevi, neoplastic transformation, eventual metastasis; target of "cancer vaccine"
Cardiovascular	NIDDM-induced small vessel disease	Polygenic disorder	Diabetic vasculitides, secondary to chronically elevated blood glucose, lead to paresthesias and neuritides; retinal angiogenesis leads to retinopathy

4.1. Diseases attributable to simple recessive Mendelian, X-linked, triplet-repeat, or mitochondrial inheritance

Many human diseases can be traced to mono- or diallelic mutations in a single gene that is crucial for homeostasis. A large class of disorders is caused by homozygous recessive mutations that cause a loss of function in a critical cellular protein, often associated with signal transduction pathways that regulate hematological function, endocrine and metabolic systems, or ion transport in epithelia or nerves. Such anomalies are notoriously difficult to treat with conventional remedies. While a deficiency in a circulating molecule such as insulin (diabetes mellitus type I) or factor IX (hemophilia B) can be, at least partially, ameliorated by exogenous administration of the deficient protein, a loss of function in a cognate receptor, intracellular enzyme, or structural protein is typically unresponsive to such therapy. Unless the mutation can be circumvented, this loss of function may present an

intractable danger to the patient's health. The ΔF508 mutation in CF – pursuant to the loss of a single phenylalanine codon in the *cftr* gene on both chromosomes – renders an otherwise functional chloride transporter incapable of reaching the plasma membrane of epithelial cells, instead occasioning its sequestration in the endoplasmic reticulum and its subsequent degradation by proteasomes. This homozygous deletion (and others like it) affects critical cellular functions such as water transport, and ultimately leads to the fatal sequelae of CF.

Similarly, familial hypercholesterolemia (FHC) is caused by mutations in both genes coding for the cell surface low-density lipoprotein (LDL) receptor; decreased or absent receptor expression prevents cellular uptake of LDL and provokes the deleteriously high levels of plasma LDL that cause accelerated atherosclerosis. A litany of enzyme deficiencies – for example, Tay–Sachs disease (hexosaminidase A); Gaucher's disease (glucocerebrosidase); Fabry disease (alpha-galactosidase A); ataxia-telangiectasia, Bloom's syndrome, and Fanconi's anemia (DNA-repair enzymes); immune system disorders such as ADA deficiency and chronic granulomatous disease (NADPH oxidase) – result in usually fatal illnesses in affected patients. The insufficiency can be partly remedied in some cases (e.g., Gaucher's, ADA deficiency, and Fabry) by continual administration of the missing enzyme as a drug; nevertheless, cures for these diseases (as through bone marrow transplants) remain exceptional and elusive. Mutations in intracellular structural proteins (muscular dystrophy), membrane components (myelin in Type Ia Charcot-Marie-Tooth syndrome), and specialized functional proteins (hemoglobin in sickle-cell anemia and thalassemia) also pose detrimental or even grave threats to the health of affected individuals.

Most of the above are examples of recessive or X-linked diseases. Some disorders transmit in families according to autosomal dominant patterns. Neurofibromatosis 1 (resulting from germline monoallelic loss of neurofibromin, a GTPase-activating protein) and Li–Fraumeni syndrome (consequent to germline monoallelic loss of one p53 allele) are both recessive at the *cellular* level, since they require two hits against a tumor-suppressor protein to manifest in a given cell. However, if one allele is mutated in the germline, then stochastic events will inevitably give rise to the loss of heterozygosity at an early age, indicative of dominant transmission. Other autosomal dominant diseases manifest through dosage effects or dominant-negative actions, thus precipitating deleterious clinical sequelae. Hereditary triplet-repeat disorders – such as Huntington's disease, fragile X syndrome, and myotonic dystrophy – are caused by the expansion of a repeated 3-base sequence, which can occur in the regulatory or coding region of the affected gene, that is amplified in the germline from one generation to the next. This amplification fosters an increasingly severe phenotype in each successive generation (so-called anticipation). Finally, mitochondrial DNA disorders – such as Leber's optic neuropathy – are passed on maternally.

The common thread in these genetic diseases is the loss of function of a critical cellular component or the accumulation of a toxic gene product (see Table 1). Because these diseases are hereditary, the molecular and cellular defect is both widespread and lifelong. Traditional drug therapy is generally ineffective against this panel of disorders. Thus, these diseases represent the canonical challenge for

gene therapy strategies, which seek to replenish or counteract the defective function in the cells of interest.

4.2. Protein aggregation diseases

The converse of the heritable loss-of-function diseases includes dominantly inherited disorders in which there is a generation of an altered form of a particular gene product that has a dominant negative effect on the normal function or a toxic gain of function. In the latter case, for example, the abnormal protein may accrue in tissues, with toxic effects. A classic case is Alzheimer's disease. Though the precise etiology is still controversial, autopsies of Alzheimer's brains show both intracellular neurofibrillary tangles, or NFTs, of the microtubule-associated *tau* protein, and extracellular deposits of beta-amyloid protein (BAP). These gene products, as well as auxiliary proteins (e.g., apolipoprotein E4 and the presenilins), are often altered in Alzheimer's disease patients, and their dysregulation is believed to contribute to NFT formation and amyloid deposition. A similar pattern is observed in other amyloid accumulation disorders (e.g., amyloid kidney disease, diabetes mellitus type II, and systemic amyloidosis), and analogous processes are suspected in other adult-onset neurodegenerative illnesses such as amyotrophic lateral sclerosis (ALS). (In ALS, a somatically mutated superoxide dismutase I (SOD-I) gene may induce the pathology.) By reducing or abrogating the production of the abnormal protein, gene therapy strategies such as antisense RNA or gene conversion could contribute enormously to the management of these disorders.

4.3. Neoplastic diseases

Cancer develops when a clonal population of somatic or germ cells possesses a combination of genetic and chromosomal aberrations that cause inappropriate cell cycling, inefficient DNA repair, loss of contact inhibition and apoptosis, and karyotypic instability. Because cancers originate in gain-of-function (oncogenic) and loss-of-function (tumor-suppressor) mutations in the genome, this class of diseases provides another potential target for gene therapy. Putative treatment strategies could focus on downregulating oncogenes or augmenting tumor-suppressor genes, or on selectively killing tumor cells directly or via enhanced T-cell-mediated cytolytic attack. Some modalities unite gene therapy with more traditional small molecule-based approaches. For example, a vector expressing an enzyme that converts a prodrug into a toxic molecule can be transduced into tissues in the vicinity of a tumor, with the result that the neoplastic cells are selectively killed. Other strategies attempt to deliver apoptotic factors selectively to cancer cells, to differentiate the neoplastic cells, or to thwart the angiogenesis that is essential for continued growth or metastasis of a tumor (Tandle *et al*., 2004) (yet another strategy, utilizing engineered adenoviruses as "oncolytic viruses" is discussed below). Cancer is an especially popular subject of gene therapy clinical trials, and many of the above methodologies have been or are currently being investigated in patients.

4.4. Cardiovascular diseases

Diseases of the heart and vascular system may be especially amenable to gene therapy strategies. Many disorders, such as the increasingly prevalent noninsulin-dependent (type II) diabetes mellitus (NIDDM), entail the attrition of blood delivery in general, and the loss of small-blood vessel capacity in particular, because of inflammation, chemical complexation, and immune-complex damage at the vessel walls – the proximate cause of the peripheral neuropathies, renal disease, susceptibility to infection, and retinopathy of NIDDM. Patients with Type II diabetes could therefore benefit from gene therapy modalities that engender targeted revascularization, as could those with myocardial ischemia or infarction from sclerosed or obstructed coronary arteries. In addition to promoting the establishment of a collateral circulation, gene therapy can facilitate the elaboration of modulatory factors that can help reduce complications like intimal proliferation and lumenal restenosis of grafted coronary vessels. New vessels produced by such protocols often suffer from reduced structural integrity and stability, but revascularization remains a promising area of research for gene therapy modalities.

4.5. Infectious diseases

The most common application of gene therapy in the realm of infectious diseases is in the production of vaccines. Inoculation against microbial infection can be achieved by the delivery of naked DNA that expresses epitopes specific for the pathogen. Viral vectors have also found utility. The same methods used to engineer viral vectors to express a missing gene can be applied to engender an immune response, by generating pathogen-specific proteins that stimulate humoral and cellular arms of the immune system. Some viruses (such as HIV) against which vaccination is desirable may be too dangerous to be administered as attenuated particles in healthy people, and strategies are therefore sought to express immunogenic epitopes in the context of other viruses. One possible frontier for gene therapy strategies may lie in confronting the increasing peril of microbial resistance to antibiotics and antiviral drugs. Persistent microbial evolution, high replication rates, and the paucity of pharmacological targets in viruses and some bacteria have combined to generate a formidable medical challenge for the coming century. Rapidly adaptable gene therapy modalities could contribute to more effective infectious disease management in the face of such challenges.

5. Requirements for safe and effective gene therapy

In the classical case of gene replacement, the objective of gene therapy is to modulate expression of a target gene, often by restoring the function of a mutated protein but sometimes by downregulating or controlling the expression of such a protein. Other applications (such as cancer therapy or angiogenesis) involve the delivery of a novel gene to kill target cells selectively, or production of a factor

to effect a change in the physiological state of a damaged tissue. These modalities must meet several demands in order to be safe and effective:

1. *Transgene persistence and long-term stable expression*
   (a) Expression of the novel locus (supplied by the gene therapy vector in targeted cells) should be both steady and long-term, with the transgene escaping degradation and epigenetic silencing.
   (b) Cells expressing the transduced gene should be protected from immune clearance.
   (It should be noted that the above two conditions apply primarily to the classical modality of gene replacement. In some applications, such as neovascularization, it may be desirable to curtail gene expression deliberately over time, while in cancer therapy a vigorous immune response may be instrumental to the treatment strategy itself.)
2. *Specific expression*
   Vectors should be directed to the target cell population of interest, and transduction of bystander tissues should be minimized.
3. *Regulated expression*
   If the dosage of a restored normal gene must be precisely controlled (e.g., a hemoglobin gene in thalassemia), the gene therapy system should include a mechanism to manipulate expression levels reliably so as to approximate the physiological state.
4. *Reliable delivery*
   Parenterally administered in vivo vectors should be sufficiently stable to reach the nucleus of target cells intact, evading plasma proteases and nucleases as well as lysosomal degradation and interferon-mediated suppression.
5. *Minimal toxicity*
   Gene therapy vectors should be minimalistic, so as to minimize both immunogenicity and direct toxicity from the vector's components.

There are nearly 100 trillion cells in an adult human body, and shuttling a bolus of the nucleic acid "drug" to its targets is a formidable challenge. To circumvent obstacles to delivery, some gene therapy efforts that address heritable genetic diseases have focused on ex vivo transduction of hematopoietic and tissue stem cells, which are then reimplanted and utilized to restore the normal protein to the affected patient. In vivo gene therapy, in which the nucleic acid is administered parenterally much like many small molecule drugs, requires the vector to home to the targeted tissues via the blood and lymphatic circulation or to be injected directly into the tissue. For both ex vivo and in vivo approaches, proper tissue targeting is essential for success. Moreover, since the immune system is designed to react to foreign proteins such as those supplied in the gene therapy vector, drug delivery strategies must be designed either to evade immune mechanisms or to achieve the effective delivery over a minimum number of treatment sessions before immune memory sets in. Finally, the pharmacodynamics and pharmacokinetics of in vivo gene therapy vectors are typically more intricate than those of small molecule drugs. Along with the traditional concerns of route of administration, plasma stability, and hepatorenal clearance, vectors must confront *immune* and *intracellular* clearance,

and one must consider the body's handling of not only the DNA or RNA "drug" itself but also the vehicle that ferries the drug into cells.

Because of their genomic modularity and innate ability to deliver genetic material into cells, viruses have become the vectors of choice for gene therapy. Recombinant DNA technology allows disparate fragments of viral genomes to be maintained on separate DNA plasmids, permitting safe and convenient manipulation that supplants viral expression cassettes with the therapeutic genes of interest. The next chapter summarizes the salient features of viral vectors that have found application in gene therapy.

Introductory Review

Gene therapy II: viral vectors and treatment modalities

J. Wesley Ulm
Harvard Medical School, Brookline, MA, USA

1. Introduction

In its classical manifestation, gene therapy exploits the capabilities of mammalian viruses – including, remarkably, a number of infectious agents notorious for their pathogenic potential in human hosts – as vehicles to deliver therapeutic nucleic acids to cells and tissues. The previous chapter introduced some basic requirements for the vectors used in gene therapy modalities, and this chapter will introduce the viral systems most commonly employed in clinical protocols. Each choice of vector exhibits a specific set of properties with regard to the maximum size of a therapeutic insert, efficiency of production in culture, tissue tropism within the host, capacity to integrate in a target cell, long-term persistence in the host, and overall toxicity. Investigators designing gene therapy protocols must weigh the benefits and shortcomings specific to each viral type in deciding which vector to use in the treatment of a particular disease. Viral vectors are in general rendered nonreplicating, which has necessitated the development of specialized tissue culture systems to generate viral particles in high titers. Furthermore, the expansion of treatment modalities available to gene therapy researchers – including RNA-based techniques such as antisense and RNA interference – has led, in recent years, to additional production systems specially tailored to maximize the therapeutic potential of these options in the setting of a clinical application.

2. Viral gene therapy vectors: applications and limitations

Only a small subset of the immense variety of animal viruses have been tested as bearers of therapeutic genes. These have been chosen primarily from among the common human pathogens with broad tissue tropism, for which detailed information on genes and sequences is available. Viruses vary considerably in size, life cycle, titer, ease of laboratory manipulation, safety, immunogenicity, and composition (and they may possess RNA or DNA genomes). Currently, nearly all gene therapy protocols use retroviruses, adenoviruses, adeno-associated viruses (AAVs), herpes viruses, or Epstein–Barr viruses (EBVs) as the gene delivery agent. The

general features, advantages, and disadvantages of each virus family are summarized in Table 1. Detailed discussions of retroviral, adenoviral, and AAV vectors are provided in other chapters; therefore, these vector systems will be only briefly summarized here.

2.1. Retroviruses

Retroviruses (family *Retroviridae*) were so named because of their "retrograde" flow of genetic information from RNA in the virion to DNA in the host cells. While many other RNA viruses exist, retroviruses stand out in their use of a DNA intermediate and in their possession of an RNA-dependent DNA polymerase called *reverse transcriptase* (RT), which generates a double-stranded complementary DNA (cDNA) from the diploid retroviral genomic template, bounded by long terminal repeats (LTRs), in the cytoplasm of an infected cell. For purposes of gene therapy, retroviruses possess another salient feature that has made them a vector of choice for gene replacement applications: As part of its replication cycle, a retrovirus's cDNA – flanked by the LTRs – integrates stably into the genome of a host cell (becoming an *integrated provirus*), a feature that greatly assists long-term retention and expression of a therapeutic transgene.

Most retroviruses can infect only actively dividing cells, a limitation that can nonetheless be an asset in anticancer modalities. However, one subgroup of the retrovirus family, the lentiviruses – which includes HIV – can productively infect resting, noncycling cells. For reasons of both safety and efficiency, retroviral vectors are generally rendered nonreplicating, with essential viral components maintained on separate plasmids lacking LTRs, or supplied in trans via complementation by *packaging cells*, which express viral gene products off genomic loci. (Lentiviral vectors are endowed with additional safety features because of their high pathogenicity in the wild (reviewed in Delenda *et al*., 2002.) Retroviral vectors have been utilized in several notable clinical trials over the past decade. In a promising recent study, Alain Fischer and colleagues in Paris used the Moloney murine leukemia virus (Mo-MLV) to transduce dividing hematopoietic progenitors of patients with a rare X-linked immune disorder, SCID-X1, caused by an inherited deficiency in the γ-c subunit of the interleukin receptor that is critical for lymphocyte maturation (Cavazzana-Calvo *et al*., 2000; Hacein-Bey-Abina *et al*., 2002) (summarized in Figure 1). A T-cell acute lymphoblastic leukemia emerged in three of the patients in the study, owing to aberrant activation of the LMO-2 protooncogenic locus consequent to proviral integration; however, these leukemias have been highly responsive to therapy, and further adjustments in the retroviral systems should help circumvent this complication. Retroviruses have also been utilized as immunotherapeutic "cancer vaccines". Melanoma cells from affected patients are isolated and transduced with a retroviral vector to produce GM-CSF, a cytokine that activates dendritic cells – a potent form of antigen-presenting cell (APC) – then reimplanted into patients to stimulate a strong and specific anti-melanoma immune response.

Table 1 Viral gene therapy vectors

Viral vector	Taxonomy and structure	Advantages	Disadvantages
Retrovirus	– Retroviridae – ssRNA viruses – Reverse-transcribe viral genome into dsDNA after entry into cells – ~7–10-kb genome – Flanked by LTRs, which mark boundary between transgenic sequence and host genome	– Reverse-transcribed DNA is integrated into host cell genome, providing the potential for long-term expression off retroviral U3 promoter or other viral or cellular promoters – Highly modular, can express *gag, pol, env* genes off separate plasmids and modify as desired – Replication-incompetent viral particles can be produced in packaging cells – No recombination steps required in construction	– Transgene integration is random, creating a danger of interfering with crucial gene expression or activating protooncogenes (recently observed in clinical trial) – Some difficulties with long-term expression – Can infect only actively dividing cells after breakdown of the nuclear envelope (except lentiviruses like HIV, which can infect resting cells)
Adenovirus	– Adenoviridae – Linear dsDNA – 30–40-kb genome – Sequential gene expression – Can infect many tissues – A cause of the common cold	– High titers and efficiency of infection – E1a, E1b, E3, E4 regions can all be substituted with therapeutic genes; multiple inserts are therefore possible – High tropism for liver (good for hepatic diseases) and various epithelia – Vectors can be complemented and packaged conveniently in 293 cells – Episomal residence and gene expression can be a safety feature	– Construction requires recombination steps owing to large size – Residual viral gene products (and transgene, to a lesser degree) elicit strong immune response against cells infected with the vector – Substantial difficulty achieving long-term expression off adenoviral episome, due to immune clearance – Potential toxicity in infected cells, especially in liver – Danger of contamination with replication-competent helper virus in preparations
Adeno-associated virus (AAV)	– Parvoviridae – Linear ssDNA – 4.5–5.5-kb genome – Flanked by ITRs	– Can transduce nondividing cells – Good transduction of CNS, muscle – Low immunogenicity – Availability of distinct serotypes that can infect different primary cell types	– Small capacity limits size of packaged insert – Difficulty in achieving large-scale production
Herpesvirus	– Herpesviridae – Linear dsDNA – Very large (150 kb) genome; latency	– Large size enables packaging of sizable inserts, for example, potentially useful for treatment of DMD (an enormous gene) – Tropic for neural tissue	– Some cellular damage observed even in replication-defective mutants – Silencing of promoters in CNS
Epstein-Barr virus (EBV)	– A herpesvirus – Circular DNA episome	– Persistence of episome makes it useful in hybrid vectors	– Low infection titers by itself, so not useful as a stand-alone gene therapy vector

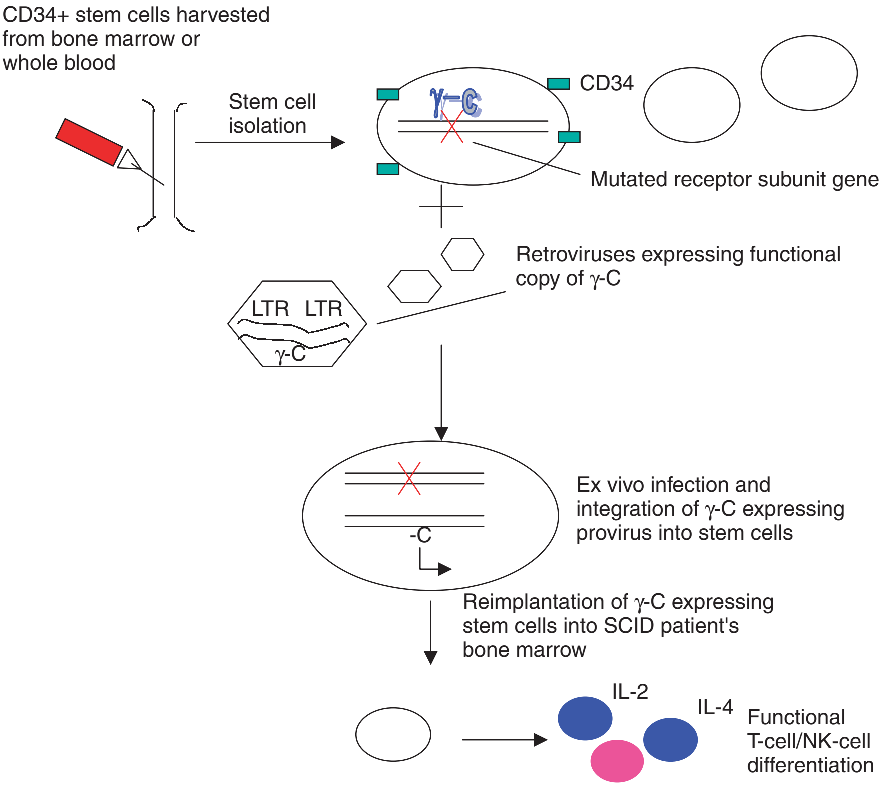

Figure 1 Stem cell-based gene therapy: Ex vivo retroviral transduction of functional γ-C receptor subunit-expressing gene into stem cells of a SCID-X1 patient. Use of the patient's own stem cells helps to obviate immune rejection of the transplanted cells, although the new gene is ectopic to its original location. It is hoped to use similar methodology for a wide array of diseases, such as Duchenne muscular dystrophy, by differentiating stem cells into other tissues. Silencing of the retroviral transgene and toxicity associated with ectopic expression of the transgene are concerns. Based on work of Alain Fischer *et al*

2.2. Adenoviruses and adeno-associated viruses

Members of the family *Adenoviridae* are large (30–40 kb), linear dsDNA viruses that are frequently implicated in human illness, causing eye and bladder disorders as well as common cold. The family is quite diverse and there is frequent recombination among different serotypes, but the general organization is the same from virus to virus. *Adenoviridae* display a complex temporal regulation of gene expression divided into early (E), delayed early (IX and Iva2), and late (L) genes, with viral genomes flanked on each side by an *inverted terminal repeat* (ITR). Unlike retroviruses, adenoviruses are double-stranded DNA viruses that do not integrate into the host genome, but remain as linear episomes in the nucleus, separate from the host's genomic DNA. Furthermore, adenoviruses are capable of infecting both resting and dividing cells.

When adenoviruses are used as gene therapy vectors, foreign DNA (up to about 7 kb) can be introduced into E1, E2, and parts of the E4 region. Adenoviruses have a large tissue host range, with an especially marked tropism for the liver. They can be produced at high titers in 293 cells, a human complementation line that supplies E1a and E1b gene products in trans; as a result, adenoviruses are convenient for the in vivo expression of an essential gene in significant quantities.

Adenoviral vectors are often used in vaccine protocols to express immunostimulatory epitopes so as to activate both humoral and cellular immunity (Imler, 1995), as well as in numerous anticancer regimens (reviewed by Zhang, 1999). For example, E1a and E1b-deleted adenoviral variants can serve as *oncolytic viruses* that selectively infect p53- and Rb-deficient neoplastic cells (tumor suppressors that are complexed by E1a and E1b in the wild). Adenoviral vectors, unfortunately, are notorious for stimulating a vigorous immune response against infected cells, and this and other factors heighten their toxicity and reduce their long-term persistence. Moreover, special care must be taken to ensure the absence of replication-competent "helper" virus in adenoviral vector preparations.

AAVs are a family of small, 4.5–5.5 kb single-stranded DNA parvoviruses flanked by ITRs. They derive their name from the fact that they require the adenoviral E1a, E1b, E2a, and E4 gene products in trans to propagate themselves, and therefore are naturally infectious only in tandem with a concurrent adenoviral infection of a target cell. In practice, since replication deficiency is desirable in a gene therapy vector, adenoviral complementation is furnished only in the cells in which the AAV vectors are initially generated. AAVs are available in multiple serotypes, which facilitates their application for targeting specific tissues, such as muscle and brain, including nondividing cells.

AAVs can integrate into target DNA like retroviruses, and are even capable of doing so in a site-specific manner. The AAV *rep* protein recognizes a cognate sequence that results in enhanced integration into a region of the long arm of chromosome 19 called the AAVS1 site. In practice, however, AAV vectors do not express *rep* upon infection of target cells, and therefore integrate randomly (like retroviruses), either as single proviruses or as head-to-tail concatemers.

2.3. Herpesviruses, Epstein-Barr virus (EBV), and nonviral systems

Herpesviruses are enormous (>150 kb) dsDNA viruses, among the largest found in nature. They are ubiquitous in human disease, herpes simplex virus (HSV)-1 causing cold sores and fever blisters, HSV-2 inducing genital pruritus and blisters, varicella-zoster virus (VZV) causing both chicken pox and shingles, and human herpes virus (HHV)-8 inducing AIDS-associated Kaposi's sarcoma. Herpesvirus recombinant vectors can accommodate up to 30 kb of inserted sequence, and so-called amplicons (which are analogous to gutless adenoviruses) can incorporate up to 150 kb of foreign DNA sequence. Thus, herpesviruses provide one of the only viable means to package very large gene cassettes, such as a cDNA for the dystrophin gene that is mutated in Duchenne muscular dystrophy. Herpesviruses are also tropic for the nervous system, which they access in nature via retrograde axonal flow from infection at a mucosal surface to residence at

a dorsal root ganglion. This property makes herpesviruses valuable for treatment modalities that must surmount the blood-brain barrier (Jacobs *et al*., 1999; Lam and Breakefield, 2000). Furthermore, their propensity to enter a state of latency following infection helps reduce immune provocation and facilitate long-term establishment in target cells. Like other vectors, herpesviruses suffer from the potential for gene silencing in transduced cells (including silencing of the "latency" promoters). Moreover, use of even nonreplicating herpesviruses can have some toxicity.

One interesting herpesvirus variant is the EBV, the pathogen that causes infectious mononucleosis. As a virus with transforming potential that is tropic for lymphocytes, EBV is also implicated in Burkitt's lymphoma and nasopharyngeal carcinoma. EBV is unusual in that it persists in infected cells as a circularized episome, and it partitions – along with the host cell genome – into dividing cells following replication. Its titers are generally low and, while it is impractical as a gene therapy vector by itself, EBV is popular as a component of so-called hybrid vectors that utilize two or more viral backbones to generate the vector. An adenoviral-EBV vector, for example, combines the high efficiency and wide host range of the adenoviruses with the episomal persistence of EBV, to forge a "virus within a virus". EBV elements are packaged within an adenoviral "shell", then excised following infection by a lox-CRE-mediated system to liberate the episome. Adenovirus- or herpesvirus-retrovirus hybrids pursue a similar objective, introducing retroviral integration elements into the genome of the adenovirus or herpesvirus to engender an integrating component.

One additional area of research involves nonviral gene therapy systems. The simplest example of such methods is the DNA vaccine, in which naked DNA is injected locally into a tissue, with subsequent cellular uptake engendering the production of relevant epitopes against a pathogenic agent (reviewed in Wiethoff and Middaugh, 2003; Parker *et al*., 2003). In general, however, nonviral systems employ more sophisticated modalities such as DNA-coated circulating microparticles to deliver a therapeutic nucleic acid bolus to affected tissues. Elements of nonviral systems generally mimic essential properties of viral vectors, which have made them useful as vehicles for therapeutic genes, such as their capacity to efficiently endocytose through plasma membranes and escape lysosomal degradation to enter cellular nuclei. Progress in nonviral vector modalities is technologically driven, strongly correlating with advances in the capacity to mass-produce sophisticated, microfabricated lipid or polymeric particles in cell-free systems. These methods are currently inefficient, but technical advances in biochemistry and microparticle engineering may soon help nonviral systems to become viable alternatives to viral-based modalities, with a greater safety margin than most viral protocols.

2.4. Antisense strategies, dsRNA, RNAi

A relatively new and promising application for gene therapy consists of a set of strategies that employ RNA molecules to inhibit specifically a gene of interest, for example, a gene whose product is toxic. Toxic proteins or peptides are thought

to be involved in degenerative diseases of the nervous system such as Huntington's disease, amyotrophic lateral sclerosis, Kreutzfeld–Jakob disease, retinitis pigmentosa, and (probably) Alzheimer's disease. In such cases, the protein or peptide accumulates (often by aggregation) at levels that are toxic to nearby neurons, and therapeutic approaches directed at minimizing the deleterious accumulation may be beneficial. Cancer is another salient target of RNA inhibitory approaches, because neoplasia inevitably involves the inappropriate and constitutive expression of growth-enhancing and cell-cycling oncogenes, whose repression by specific downregulating RNA molecules could furnish a means to selectively target and kill neoplastic cells. In addition, RNA inhibitory strategies against cancer may be more adaptable than other modalities in treating cancer relapses due to new mutations in tumor cells, because an RNA molecule that targets its novel (mutated) complement is far easier to generate than a small molecule or peptide that targets a protein. Finally, RNA inhibition could potentially yield a rich harvest of new antimicrobial drugs that are targeted against the wealth of unique gene products present in foreign pathogens.

From a physiological perspective, "RNA inhibition" consists of a series of conserved mechanisms, in both prokaryotes and eukaryotes, which regulate gene expression and combat viral infection by modulating mRNA amounts and controlling the levels of mRNA translation (see reviews by Hannon, 2002; Inouye, 1988; Brantl, 2002). RNA inhibition entails two overlapping yet distinct phenomena – (1) antisense RNA and (2) RNA interference or RNAi. (The action of ribozymes, in which catalytic RNA cleaves an RNA target in cis or in trans, is also related to these phenomena.) There is occasional confusion between the two, in part because of their similarities, but antisense RNA is not the same as RNAi and, in fact, the latter was discovered as a consequence of work on the former.

The principle of antisense RNA is elementary, relying on the ability of RNA, like DNA, to form duplexes. Thus, an RNA transcript elaborated from the antiparallel strand of an open reading frame in the genome will hybridize to the mRNA produced upon activation of transcription at that gene. Watson–Crick pairing of a capped and polyadenylated message with its complement can then interfere with mRNA processes, ribosome interactions, and/or the docking of translation initiation factors, effectively rendering the mRNA incompetent for peptide production. Interaction of a transcript with its antisense sequence can also promote RNAse H–mediated degradation of the message (Figure 2). The principle of antisense inhibition was established in the early 1980s, and it found utility as a laboratory tool for selective blocking of gene expression in a wide variety of organisms (Dolnick, 1997). Eukaryotic antisense transcripts have been implicated in the phenomenon of genomic imprinting, which involves the selective, epigenetic downregulation of alleles specific to the paternal or maternal chromosome (Ward and Dutton, 1998). Antisense RNA approaches have been recently applied in the clinic; fomivirsen is a recently approved antisense RNA used to treat retinitis caused by cytomegalovirus in patients immunocompromised by HIV infection.

Like antisense RNA, RNAi requires the formation of a dsRNA structure. Otherwise, however, the two mechanisms are remarkably different. A dsRNA substrate, several hundred base pairs in length, can be processed by a dsRNA-specific endonuclease, called *Dicer*, into short fragments approximately 20-bp long. These

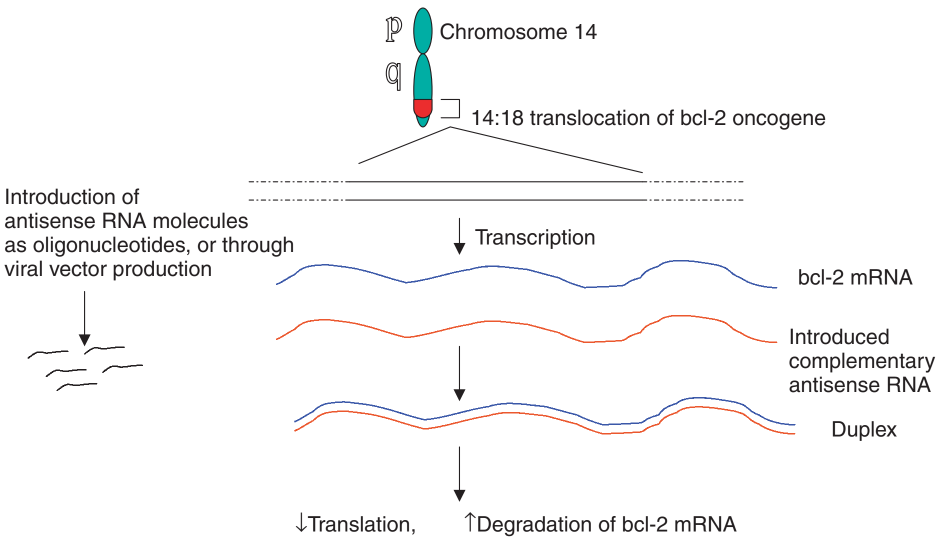

Figure 2 Use of an exogenous antisense RNA molecule to block production of an oncogenic gene product

short dsRNAs, called siRNAs (for small interfering RNA particles), are the active species in RNAi. The siRNAs form a triplex RNA structure with homologous mRNAs, and these complexes draw the attention of the RISC (RNA-induced silencing complex) array, which digests the target mRNA. In this way, mRNAs identical or homologous to the siRNAs are selectively degraded. RNAi has been shown to be operational across many species, including plants, *Caenorhabditis elegans*, *Drosophila*, and mammals.

RNA inhibition strategies represent a potentially exciting frontier because of their power and selectivity in downregulating target genes. One drawback, of course, is that they act primarily at the level of elaborated RNA transcripts rather than the genome itself. Thus, continuous administration would be required to inhibit a targeted gene chronically. RNA inhibition also represses gene expression incompletely, and as with all gene therapy strategies, successful delivery is a serious challenge. Nonetheless, the RNAi approach embodies many of the facets that make gene therapy so potentially valuable – in particular, the ability to modify the drug rapidly and adapt it to changes (such as mutations) in disease targets. RNAi has already demonstrated promise in cell culture, thwarting the infection of cells by HIV and polio virus (Coburn and Cullen, 2002; Gitlin *et al*., 2002; Hu *et al*., 2002). Moreover, the Dicer-directed endonuclease-processing step can be bypassed to enable direct synthesis and utilization of the active siRNA, and methodologies to express siRNA species directly off polIII or phage promoters may permit continuous expression of these inhibitory molecules in cells of interest.

2.5. *In situ gene correction*

An additional frontier for the gene therapy field involves the use of specialized vectors to engender the repair of nonfunctional gene targets in vivo and in situ. In

most gene replacement strategies – envisaged and implemented for diseases such as cystic fibrosis, hemophilia, and sickle cell anemia – the viral vector expresses the missing or defective gene *ectopically*, outside the native genomic location of the gene in normal cells. This can occur either as an integrated provirus (as for retroviruses) randomly integrated into a chromosome or as an intranuclear, nonintegrated episome for vectors such as adenoviruses. Such ectopic expression, however, can be problematic since the physical location of a gene in normal cells is often germane to its expression levels, regulation, and integration into signal transduction networks. Epigenetic mechanisms like chromatin remodeling, methylation, and histone acetylation are often critical factors in the precise modulation of gene expression that is seen in vivo, and such controls may not be operative if a gene integrates into a different chromosomal site or resides on an episome. Careful regulation of expression is especially crucial in many hematological and endocrine disorders, whose sine qua non is the loss or mutation of a protein whose dosage levels are normally maintained within narrow limits to ensure proper physiological function and response to stresses.

To achieve gene correction in situ, a gene therapy vector would not carry an intact expression cassette to be integrated or episomally expressed; rather, it would furnish a *repair template* oligonucleotide containing a section of the gene that is mutated or deleted, possibly in conjunction with specialized proteins involved in homologous recombination, mismatch repair, or other cellular processes that participate in DNA modification or double-strand break (DSB) formation and repair. The human equivalents of the Rad52 epistasis group proteins, found in yeast, are central players in the repair of cellular DSBs and have thus attracted interest as potential facilitators of gene correction.

One possible methodology to effect such correction is afforded through the use of AAV vectors, which have been used successfully to perform gene targeting in mammalian cells (Russell and Hirata, 1998). While targeting efficiency is still low (approximately 1%), further knowledge of the mechanisms involved in such AAV-mediated repair may enable far higher rates of gene conversion. Indeed, recent work has suggested that AAV-driven correction is greatly enhanced in the presence of induced DSBs (Miller *et al*., 2004), and techniques to induce site-specific DSBs in the genome – through the use of "meganucleases" such as the I-SceI endonuclease, which recognize an 18-bp sequence that can be unique even within the large human genome – can potentially augment gene correction levels even further. The precise mechanism through which a single- or double-stranded DNA-repair template finds its target within the genome is unclear, though it may ensue from transient Watson–Crick base pairing between the oligonucleotide and the complementary strand of a genomic duplex, which has temporarily unwound due to stochastic "breathing" and opening of the two strands.

Another proposed yet highly controversial scheme to effect gene correction involves a technique dubbed *chimeraplasty* (Cole-Strauss *et al*., 1996). This modality uses a unique oligonucleotide consisting of a double-stranded RNA-DNA hybrid, in which the corrective bases in the DNA of one strand are flanked by RNA bases – often chemically modified – and paired with a DNA complement. The modification was claimed to both bolster stability of the repair template (protecting it from exonuclease digestion) as well as to augment its capacity

to base pair with a mutated target. The chimeraplast, paired with its genomic target, would then constitute a substrate to attract DNA-repair machinery (perhaps mismatch repair proteins), which would then correct the mutated base pair to result in the proper sequence. Early reports had suggested gene conversion levels of up to 50% in cells with the sickle-cell anemia mutation, yet the chimeraplasty field has been surrounded by controversy since later studies have shown mixed results in substantiating the original findings (see review by Taubes, 2002). The chimeraplastic oligos are difficult to synthesize and apply, and many laboratories have reported a degree of gene correction but at much lower levels. A recent study in plants has suggested that at least a portion of the correction originally attributed to the chimeraplasts may in fact ensue from spontaneous mutation (Ruiter *et al*., 2003).

The prospect of in situ gene correction remains a promising, yet thus far unrealized approach to specific and efficacious gene therapy. As with many other gene therapy modalities, the intriguing conceptual basis of this methodology is hampered in practice by mundane issues of delivery and efficiency within the cell. Many of the processes that underlie gene correction remain poorly defined, just as in more established therapies that involve retroviral transgene or adenoviral episome persistence. The most fruitful avenues to advance these modalities to clinical applicability may therefore reside in basic science investigations that better elucidate the underlying mechanisms, enabling them to be more effectively exploited in specific treatments.

3. Conclusion

Modern medicine stands at the precipice of an entirely new pharmacology. For the first time in history, physicians seek to manage disease at the level of the genetic information that underlies all biology. The promise of this technology resides in its potentially magnificent specificity and high therapeutic index, as well as in the potential for rapid adaptation of therapies on an individualized basis. This latter property may be especially valuable in confronting cancer and a wide array of infectious diseases, for, as has become evident over the past several decades, natural selection is as operative in microbial and cellular pathology as it is in animal biology. The success of new chemotherapeutic drugs is too often attenuated or overcome altogether by the rise of resistant clones; the long-term solution to this challenge may be the capacity on the part of the clinician to respond just as rapidly. Currently, gene therapy faces significant hurdles in terms of vector delivery, stable transgene expression, and safety. But as work to overcome these obstacles progresses, the potential for both ex vivo and in vivo gene therapy comes closer to realization and clinical application.

Specialist Review

Hematopoietic stem cell gene therapy

Adrian J. Thrasher

Institute of Child Health, London, UK

Fabio Candotti

National Institutes of Health, Bethesda, MD, USA

1. Introduction

Hematopoietic stem cell (HSC) transplantation is an established curative procedure for a variety of inherited disorders including hemoglobinopathies, immunodeficiencies, lysosomal storage diseases, and bone marrow failure syndromes. However, the high incidence of adverse immunologic effects associated with transplantation of allogeneic cells, including graft rejection and graft versus host disease, remains problematic. Since the early development of viral vectors as efficient tools for gene transfer into mammalian cells, autologous HSCs have been attractive targets for the development of alternative strategies based on gene correction or augmentation. Targeting human HSCs has been, and continues to be, a challenging task for several reasons. The identification of human HSCs, which themselves are heterogeneous, is difficult, and stringent purification methods that are easily transferable to the clinical setting are currently not available. Most strategies utilize cell populations that are enriched for HSC by selection of cells expressing the CD34 cell surface antigen by magnetic bead sorting. Even so, the large number of CD34+ cells that is required to achieve successful engraftment complicates the transduction process, and has implications for the development of toxicity arising from insertional mutagenesis (due to the large number of unique integration events in each graft). The identification of improved selection strategies for HSCs is therefore of significant importance.

Effective gene transfer to HSC and their progeny requires stability, which currently can only be achieved efficiently using integrating vectors, most commonly based on mammalian retroviruses (*see* Article 98, **Retro/lentiviral vectors**, Volume 2). Though effective, this leads to difficulties associated with variegation of transgene expression (dependent on the local chromatin environment), and potential for harmful mutagenesis (Baum *et al*., 2004; Challita and Kohn, 1994; Klug *et al*., 2000; Yao *et al*., 2004). Efficient transduction of a variety of primary hematopoietic cells can be achieved with vectors based on gammaretroviruses, lentiviruses, and

foamy viruses. At the time of writing, almost all clinical studies have employed murine gammaretroviruses, which are dependent on active proliferation of the target cell population for effective gene transfer because the nuclear membrane must be disrupted for entry of the preintegration complex. As HSCs are mostly quiescent, extensive studies have been dedicated to the identification of optimal ex vivo culture conditions that stimulate HSC proliferation, without inducing differentiation and loss of long-term repopulating ability. Though far from perfect, most protocols in current clinical use employ a combination of cytokines such as interleukin (IL)-3, IL-6, stem cell factor (SCF), thrombopoietin, and Flt-3 ligand, increasingly with defined serum-free culture conditions. The manipulation of cells with alternative molecules such as the homeodomain-containing transcription factor HOXB4 and bone morphogenetic protein (BMP)-4 has shown some promise, and may permit amplification of HSC populations (Bhatia *et al*., 1999; Sorrentino, 2004). Vectors based on lentiviruses and foamy viruses are under intense investigation as alternatives to murine gammaretroviruses as they are less dependent on cell division for effective gene transfer, and are highly efficient (Ailles *et al*., 2002; Case *et al*., 1999; Demaison *et al*., 2002; Josephson *et al*., 2002; Piacibello *et al*., 2002; Vassilopoulos *et al*., 2001). Clinical trials employing HIV-1-based lentiviral vectors for transduction of HSC are imminent.

2. Primary immunodeficiencies as models for HSC gene therapy

Primary immunodeficiencies (PID) are a heterogeneous group of disorders in which inherited genetic defects compromise host immunity (Fischer, 2004). The most severe forms of PID are known as severe combined immunodeficiency (SCID), in which T-lymphocyte development is invariably compromised, and associated with diverse disorders of development and functionality of B lymphocytes, and natural killer (NK) cells (Buckley, 2004). Although clinically severe, bone marrow transplantation is usually highly successful if a genotypically matched family donor or unrelated donor is available (Antoine *et al*., 2003; Buckley *et al*., 1999). However, for the majority of individuals, this is not the case, and survival from mismatched family (usually parental donor) transplants is substantially lower, and associated with predictable toxicity arising from the administration of chemotherapeutic agents to ensure adequate HSC engraftment. SCID is a particularly attractive target for gene therapy as a profound growth and survival advantage is conferred to corrected cells (though this may be variable between different molecular types). In other words, owing to the huge proliferative capacity of the hematopoietic system (and particularly the lymphoid compartment), effective gene transfer to a small proportion of bone marrow precursor cells can result in substantial correction of the immunological deficit. This is most clearly witnessed by the renewed development of lymphocytes in patients with rare somatic gene reversion events (Hirschhorn, 2003). Other primary immune deficiencies may be immediately less severe, but are associated with significant accumulative morbidity and mortality. The difficulties associated with conventional HSC transplantation

have, therefore, driven the development of novel gene therapy strategies that have recently produced remarkable clinical effects.

2.1. Adenosine deaminase deficiency (ADA-D)

Deficiency of the purine salvage enzyme adenosine deaminase (ADA) accounts for approximately 10–20% of all SCID. ADA catalyzes the deamination of deoxyadenosine (dAdo), and adenosine to deoxyinosine and inosine respectively. Deficiency of ADA leads to the accumulation of the metabolites deoxyATP (dATP) and dAdo, which have profound effects on lymphocyte development and function through a number of cellular mechanisms. There is variation in the severity of the condition but most ADA patients have very low numbers of T and B lymphocytes. An alternative modality of treatment to that of HSC transplantation is regular exogenous enzyme replacement with polyethylene glycol-conjugated bovine ADA. This can result in correction of metabolic and immunological abnormalities albeit only partially in a significant number of cases (Hershfield, 2004). The first human gene therapy studies were conducted on patients with ADA deficiency in the early 1990s (Blaese *et al*., 1995; Bordignon *et al*., 1995; Hoogerbrugge *et al*., 1996; Kohn *et al*., 1998). Peripheral blood lymphocytes and/or HSCs were used as targets for gammaretroviral vector-mediated gene transfer, and though overall results were disappointing, long-term persistence of transduced cells was clearly demonstrated (Muul *et al*., 2003; Schmidt *et al*., 2003). The most important reason for the limited success of these studies was probably the continued administration of PEG-ADA. This compromised the efficient engraftment and development of transduced cells by removing their selective growth and survival advantage over nontransduced counterparts. This suggestion is supported by evidence of increasing levels of transduced peripheral blood T lymphocytes in two patients in whom PEG-ADA was discontinued sometime after gene therapy (Aiuti *et al*., 2002b; Kohn *et al*., 1998). Furthermore, results from a new study have clearly demonstrated that ADA-SCID can be successfully treated by gammaretroviral vector-mediated gene therapy in the absence of concomitant enzyme replacement (Aiuti *et al*., 2002a).

In this recent successful study, two important changes were incorporated into the protocol that may have influenced the positive outcome. First, patients were not commenced on PEG-ADA (or PEG-ADA was discontinued), and second, patients received low-intensity myelosuppressive bone marrow conditioning using an alkylating agent to facilitate engraftment of transduced cells (4 mg kg^{-1} of Busulphan as 2 mg kg^{-1} on two successive days). All patients treated to date have demonstrated an impressive recovery of immunological function, directly attributable to the development of new immunologically competent cells from transduced precursors (the absolute requirement for a conditioning procedure has not been rigorously tested in clinical trials. However, two additional recent studies in which transduced cells were administered concomitantly or after withdrawal of PEG-ADA, in the absence of prior chemotherapy, have not resulted in significant clinical recovery). Some variability in the levels of recovery may reflect the effectiveness of bone marrow suppression, or the dose of transduced cells in individual patients. However, in all cases, there has been impressive correction of

the metabolic defects, comparable to that achieved following successful allogeneic bone marrow transplantation. Importantly, there is also clear evidence for stable transduction of multipotent HSCs. This has positive implications for the treatment of other hematopoietic disorders where similar levels of engraftment would be predicted to result in therapeutic benefit. A second similar study using a gibbon-ape leukemia virus (GALV)-pseudotyped gammaretrovirus incorporating the spleen focus forming virus (SFFV) LTR, and the Woodchuck posttranscriptional regulatory element (WPRE) in order to force maximal expression of ADA in transduced cells (and therefore to achieve maximal systemic detoxification) has also reported good clinical effects. In this case, an alternative conditioning regimen using melphalan (140 mg m^{-2} as a single dose) was employed, although it is too early to draw meaningful comparisons between the two studies.

2.2. *X-linked severe combined immunodeficiency (SCID-X1)*

X-linked severe combined immunodeficiency (SCID-X1) accounts for approximately 50–60% of all SCID, and is caused by mutations in the gene encoding the common cytokine receptor gamma chain (γc). This is a subunit of the cytokine receptor complex for interleukins (IL) 2, 4, 7, 9, 15, and 21. In the absence of γc signaling, many aspects of immune cell development and function are compromised. The classical immunophenotype of SCID-X1 is the absence of T and NK cells, and persistence of dysfunctional B cells (T-B+NK-SCID). If a genotypically matched donor is available, bone marrow transplantation is a highly successful procedure with a long-term survival rate of over 90%. The high survival rates are partly due to the fact that the absence of T and NK cells in SCID-X1 patients allows engraftment in the absence of myelosuppressive conditioning.

Many incremental advances in gene transfer technology have contributed to the successful application of gene therapy for SCID-X1 and ADA-D (including the optimization of cell culture and gene transfer conditions ex vivo), which complement the intrinsic profound selective growth advantage imparted to successfully transduced cells (for SCID-X1, this is probably even more potent than that observed following restoration of ADA activity). The first dramatic demonstration of effective somatic gene therapy in human disease was derived from a study on patients with SCID-X1 (Cavazzana-Calvo *et al*., 2000; Hacein-Bey-Abina *et al*., 2002). Here, an amphotropic gammaretroviral vector encoding a γc cDNA (regulated by Moloney murine leukemia virus long terminal repeat sequences) was used to transduce autologous $CD34^+$ cells ex vivo, which were reinfused into the patients in the absence of preconditioning (see Figure 1). In nearly all patients, NK cells appeared between 2 and 4 weeks after infusion of cells, followed by new thymic T-lymphocyte emigrants at 10–12 weeks. With some variation, the number and distribution of these T cells normalized rapidly (more rapidly than observed following haploidentical transplantation). They also appeared to function normally in terms of proliferative response to mitogens, T-cell receptor (TCR), and specific antigen stimulation, and to have a complex phenotypic and molecular diversity of TCR. Functionality of the humoral system was also restored, maybe not quite as effectively, but to a sufficient degree that discontinuation of immunoglobulin therapy

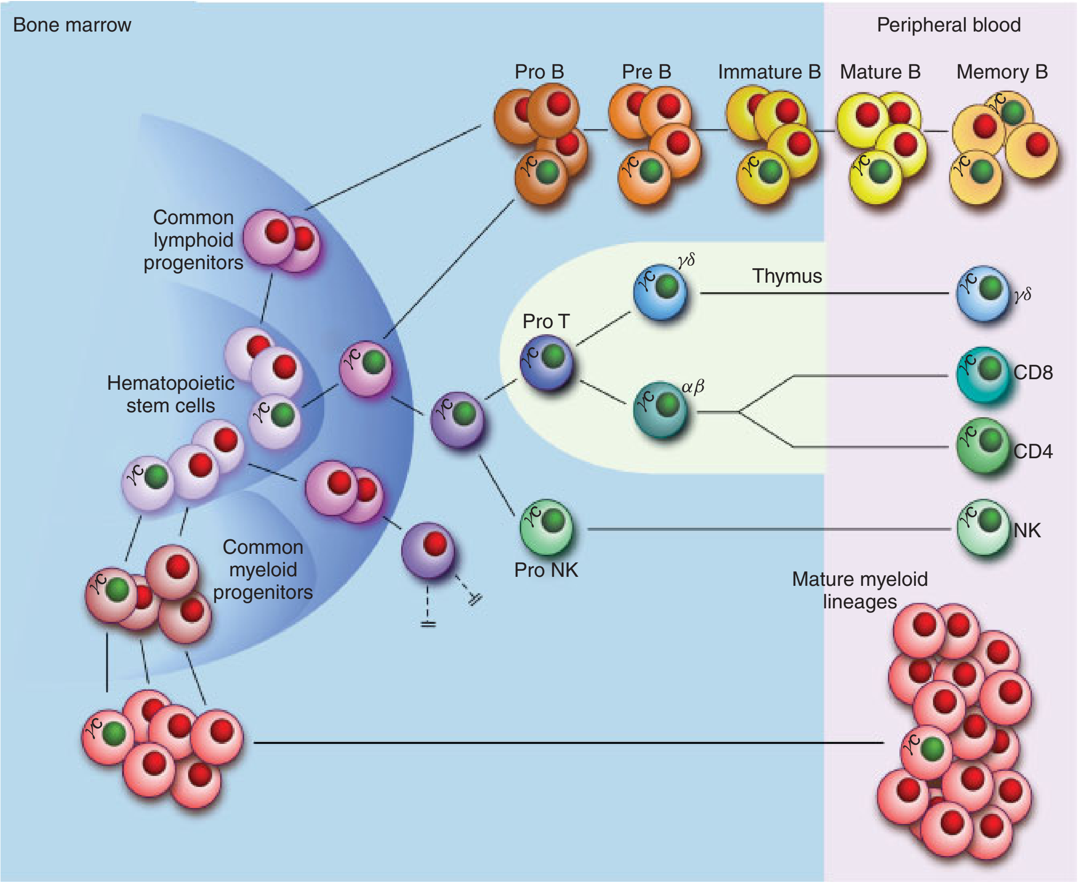

Figure 1 Schematic representation of the effects of gene therapy for SCID-X1 as demonstrated in recent clinical trials. In the absence of γc, T lymphocyte and natural killer (NK) cell differentiation is compromised, but when functionally corrected by transduction of some HSCs, the profound growth and survival advantage imparted to progenitors allows the differentiation and development of large numbers of mature circulating T and NK cells expressing the transgene. In human patients, B-lymphocyte differentiation occurs relatively normally in the absence of γc expression, although the cells have intrinsic functional defects. Gene-corrected B-cell lineages therefore do not appear to have clear selective advantage over mutated counterparts until the stage of "memory B cell" where some accumulation of γc-expressing cells has been reported. Restoration of γc expression to myeloid cells does not confer any selective advantage, and they differentiate normally in its absence. In this population, gene-corrected cells are, therefore, found at low levels (particularly because no preconditioning has been administered to patients to enhance HSC engraftment). Expression of functional γc is marked on gene-corrected cells (green nuclei). Nontransduced host cells are also shown (red nuclei)

was possible in most patients. A second study using a GALV-pseudotyped gammaretroviral vector and serum-free culture conditions has produced similar results (Gaspar *et al*., 2004). Persistent long-term marking in myeloid cells, albeit at low level, suggests that long-lived stem or progenitor cells have also been successfully transduced. The contribution to the initial burst of thymopoiesis from relatively late T-cell precursors in the original transduced CD34+ cell population, versus that from cells earlier in the hematopoietic differentiation hierarchy (or true HSCs)

that have engrafted in the bone marrow, has not yet been determined. This may have important implications for the durability of immunological reconstitution, and for sustained production of new T cells. Ultimately, the longevity of functional reconstitution can only be determined by clinical monitoring, but it may also be feasible to repeat gene therapy on multiple occasions. Definition of the effective window within which gene therapy will be effective is vitally important, as true for other more conventional therapeutic modalities. This has been clearly demonstrated by the failure of immunological reconstitution in two older patients following effective gene transfer to bone marrow CD34+ cells (Thrasher *et al*., 2005). At least for SCID, it is likely that there are host-related restrictions to efficacy, for example, due to the inability to reinitiate an exhausted or failed program of thymopoiesis.

2.3. Other forms of SCID as targets for gene therapy

The molecular basis of autosomal recessive T-B+NK-SCID is mutation of the receptor tyrosine kinase gene *JAK-3*. The dependence of γc on signaling through JAK-3 is responsible for a clinical and immunological phenotype identical to that of SCID-X1, and the rationale for gene therapy is, therefore, similar. Correction of a murine model of JAK-3 deficient SCID has been achieved using both myelosuppresssive, and more relevant to clinical studies, conditioning-free protocols (Bunting *et al*., 2000). Patients with mutations of the recombinase-activating genes *RAG-1* and *RAG-2* characteristically present with absence of both B and T cells. Murine gammaretroviral vectors have been shown to effectively reconstitute RAG-2 deficient mice in the absence of detectable toxicity, even though gene expression was not tightly regulated (Yates *et al*., 2002). One way to obviate toxicity arising from dysregulated gene expression in any condition, and to achieve physiological activity, is to correct genetic mutation by gene repair or homologous recombination. It has recently been shown that RAG2−/− mutant murine embryonic stem (ES) cells, repaired by standard homologous recombination technology, can be grown in vitro to provide sufficient hematopoietic progenitors for engraftment and correction of RAG-2 mutant mice (Rideout *et al*., 2002). This is the first example of gene therapy combined with a therapeutic cloning strategy, and clearly has important implications for future treatment of many genetic disorders.

2.4. Other primary immunodeficiencies as targets for gene therapy

Chronic granulomatous disease (CGD) is caused by mutations in genes encoding components of the phagocyte NADPH-oxidase complex, which is responsible for mediating efficient killing and digestion of many bacteria and fungi. In many ways, this has become a model disorder for testing HSC gene therapy strategies, as there is no growth or survival advantage for corrected cells (Barese *et al*., 2004; Malech, 1999). Gene expression is also only important in relatively short-lived terminally differentiated effector cells such as neutrophils and macrophages, meaning that long-term efficacy is entirely dependent on efficient stable transduction of HSCs. Important information can be obtained from the study of variant patients, who

retain partial NADPH-oxidase activity, and carriers of the X-linked form of the disease. From these, it can be predicted that over 10% correction in terms of cell numbers will be therapeutically effective, but that levels of correction per cell (in other words, the levels of enzyme activity) probably needs to be more than 30%. Therefore, the challenges are to achieve sufficient engraftment of transduced HSC, and efficient gene expression in terminally differentiated cells. Several clinical studies have been performed using standard gammaretroviral vectors, but in the absence of bone marrow preconditioning, only transient low-level correction has been achieved (Malech *et al*., 1997). More recently, studies have been initiated using low-intensity conditioning (busulphan or melphalan as for ADA gene therapy studies) to create space for incoming transduced HSC. These have provided good evidence for substantial correction associated with genuine therapeutic effect (clearance of infections), although prolonged follow-up is necessary to determine durability (communication from Dr. Manuel Grez, European Society for Gene Therapy meeting, 2004). It is likely that ongoing improvements in vector type and design will facilitate reliable high-level correction of this disease. Progress in gene transfer strategies for CGD will likely be directly translated to similar approaches for diseases such as Leukocyte Adhesion Deficiency type 1 (LAD-1), an inherited disorder of leukocyte function caused by defective expression of the common β_2-integrin subunit (CD18). As in CGD, no survival advantage is expected in gene-corrected cells and the critical cell population to be targeted is terminally differentiated neutrophils. As for CGD, one previous attempt at treating this disease by gammaretrovirus vector-mediated transfer into HSC, and engraftment into nonmyelosuppressed recipient patients resulted in only minimal and transient correction of myeloid cells (Bauer and Hickstein, 2000; Malech, 1999). The Wiskott–Aldrich syndrome (WAS) is also classed as a primary immunodeficiency, although an invariable feature is nonimmune microthrombocytopenia. The WAS protein (WASp) is expressed in all hematopoietic cell types, and is responsible for regulated organization of the actin cytoskeleton. For this disease, efficient expression of transgene must be achieved in multiple hematopoietic lineages, at levels that correct (at least partially) the cytoskeletal defect, without toxicity that may arise from overexpression. Regulation of near-physiological gene expression is, therefore, of key importance, and has implications for selection of vector and vector design. Following several studies demonstrating correction of cellular defects in WASp-deficient mice, clinical trials for treatment of patients with this disorder are planned for the near future (Charrier *et al*., 2005; Dupre *et al*., 2004; Klein *et al*., 2003; Strom *et al*., 2003).

3. Other applications of gene transfer to HSCs

Though rare, PID offer good models on which to study gene therapy strategies for other more common diseases such as beta thalassemia and sickle-cell disease (Persons and Tisdale, 2004; Sadelain, 2002). Each disease has its own unique requirement for achieving adequate levels of correction, and for correct regulation of gene expression. Considerable thought therefore needs to be invested in the design of safe but effective patient conditioning protocols, as most applications

will not benefit from preferential outgrowth of transduced cells. It may also be possible to select pharmacologically for transduced HSC in vivo as has been shown in animal studies using drug resistance genes such as methylguanine methyltransferase (MGMT) (Milsom and Fairbairn, 2004). MGMT encodes a DNA-repair enzyme that confers resistance to the combination of the MGMT inhibitor O(6)-benzylguanine (O(6)BG) and nitrosourea drugs such as carmustine, and methylating agents such as temozolomide (Neff *et al*., 2005). This strategy may therefore have utility for chemoprotection of bone marrow in cancer studies, as well as for the forced selection in vivo of cells cotransduced with a therapeutic transgene. Alternatively, the level of gene-corrected cells can be amplified in vivo without the need for myelosuppression using selective amplifier genes (SAGs). These are chimeric molecules that allow specific pharmacological agents to trigger selective proliferation of gene-modified cells. Preliminary experiments in mice and nonhuman primates have indicated the feasibility of such an approach, and the applicability to HSC diseases such as CGD (Hara *et al*., 2004; Neff and Blau, 2001; Ueda *et al*., 2004). Some genes will, in addition, require complex regulation, which may create profound challenges for vector design (*see* Article 104, **Control of transgene expression in mammalian cells**, Volume 2). For beta-thalassemia, significant advances have been made using lentiviral vectors to obtain high-level expression of complex globin gene cassettes. Therapeutic correction in murine models of both beta-thalassemia and sickle-cell anemia has been achieved using this approach (Hanawa *et al*., 2004; Imren *et al*., 2004; May *et al*., 2000; Puthenveetil *et al*., 2004). HSC and their progeny can be used as vehicles for disseminating therapeutic gene products throughout tissues such as the central nervous system. Such a strategy is under investigation for treatment of lysosomal storage disorders such as metachromatic leukodystrophy (MLD) and Gaucher disease type 1, and the peroxisomal disorder, adrenoleukodystrophy (ALD) (Benhamida *et al*., 2003; Biffi *et al*., 2004). Similarly, HSCs are considered good targets for augmentation with genes that will promote resistance of progeny to infection by pathogenic viruses such as HIV (Fanning *et al*., 2003).

4. Insertional mutagenesis and risks of HSC gene therapy

The dependence of retroviruses on chromosomal integration for stability of transduction brings with it the risk of insertional mutagenesis. On the basis of numerous animal studies and over 300 clinical trials in which patients have received gammaretroviral vectors, the risk of clinically manifesting insertional mutagenesis has been judged to be low. However, reproducible leukemogenesis and oncogenesis have now clearly been demonstrated in preclinical models, and may be directly associated with vector dose or cell copy number. Cooperating effects from expression of the transgene, or from other elements within the vector backbone may also be important, and are likely to be context dependent (Baum *et al*., 2004). In human clinical trials, three patients with SCID-X1 having initially achieved successful immunological reconstitution developed T-cell lymphoproliferative disease approximately 3 years after the gene therapy procedure (Hacein-Bey-Abina *et al*., 2003). In at least two of these patients, retroviral vector insertion into or near the *LMO-2*

proto-oncogene resulted in high-level expression of LMO-2 in the clones, as a result of retroviral enhancer-mediated activation of transcription. Activation of LMO-2 is known to participate in human leukemogenesis by chromosomal translocation, and results in the development of T-cell lymphoproliferation and leukemia in mice, albeit with a long latency. It is therefore likely that other contributing factors are required for these events to manifest. One consideration is a contribution from the activity of the γc transgene, although there is currently no evidence of dysregulated expression in lymphoid cells. Interestingly, at least one tumor derived in susceptible mice following infection with replication gammaretroviruses has been shown to harbor separate but coincident integrations at the γc and LMO-2 gene loci, suggesting that there may be a significant synergistic interaction (Dave *et al*., 2004). Cells with high proliferative potential such as HSC and thymocytes are also likely to be more susceptible to transformation following an insertional event than quiescent cells if they acquire additional adverse mutations unrelated to the gene therapy itself.

5. Future prospects for HSC gene therapy

Much can be done to improve efficiency and safety of current protocols. The design of vectors used for gene delivery is clearly important and modifications may be possible that will limit the risks of mutagenesis, for example, by incorporation of DNA and RNA insulator sequences in integrating vectors, by the use of self-inactivating vectors (in which the powerful viral LTR enhancer sequences are deleted), or by targeting safe regions in the genome. The detailed molecular analysis of insertion events in patients undergoing HSC gene therapy will greatly assist in the delineation of favored integration points within the genome, but is unlikely to be able to predict potential for mutagenesis unless recurrent hotspots associated with clinical disease become evident. Patterns of integration into host chromosomes are also to some degree vector dependent and could thereby contribute to the likelihood of inadvertent gene activation. For example, gammaretroviruses have been shown to integrate preferentially around the transcriptional start site of genes. Methods to minimize the number of integration events per cell, and to limit the number of engrafting clones by more stringent purification of HSC populations, may therefore be beneficial. Elimination of powerful viral enhancer sequences that can dysregulate gene expression over large chromatin domains, and replacement with more physiological and tissue specific regulatory elements may be feasible, and is under investigation for several applications. Lentiviral vectors in particular, provide greater capacity for incorporation of more complex and physiological regulatory sequences. The relative risk for each type of vector modification needs to be determined in clinically relevant animal-model systems and the effectiveness of these models to predict side effects in humans will have to be validated. The development of homologous recombination or gene repair to correct mutations, or the construction of mitotically stable extrachromosomal vectors would obviate many of these problems, but current technologies are inefficient. The applicability of any novel therapy, including HSC gene therapy, ultimately depends on the balance of risks against those of alternative treatments. The accurate characterization of adverse events, the utilization of protocols to test toxicity in a rigorous way, and

the development of methods to minimize risks yet retaining efficacy are therefore essential.

Specialist Review

Gene therapy in the central nervous system

Shyam Goverdhana, Maria G. Castro and Pedro R. Lowenstein

Cedars-Sinai Medical Center, University of California, Los Angeles, CA, USA

1. Obstacles in gene delivery to the CNS: structural and innate barriers

The brain is separated from the circulating bloodstream by the blood brain barrier (BBB). The BBB is a selective physical barrier formed by endothelial cells that display tight junctions of high electrical resistance providing an effective barrier against the entry of large and highly polar compounds. Accessing the brain requires crossing through the BBB or via the cerebrospinal fluid that circulates within the CNS (central nervous system) or through direct injection into the brain.

Approaches to cross the BBB to deliver viral vectors or chemotherapeutic agents to the brain parenchyma are osmotic disruption of the BBB, administration of vasomodulator compounds, and targeted vector administration via specific receptor binding. Osmotic BBB disruption approach has been employed in animal studies (Neuwelt *et al*., 1999) and also used in the clinic to promote enhanced chemotherapeutic agent delivery. Osmotic disruption facilitates transient BBB disruption by opening of the BBB to water-soluble drugs and macromolecules in vivo, and is achieved by infusing a hypertonic solution of arabinose or mannitol into the carotid artery (Neuwelt *et al*., 1980; Kaya *et al*., 2004; Sato *et al*., 1998; Liu *et al*., 2001). BBB opening involves widening of tight junctions between endothelial cells of the cerebralvasculature and is mediated by endothelial cell shrinkage and vascular dilatation. Only transient opening of the BBB is achieved, and there is restricted delivery in the vicinity of administration. In contrast to targeted delivery, systemic delivery provides only minimal benefit as this approach lacks specificity and can induce systemic toxicity via the immune system. The viral vector cannot be selectively delivered to the target brain area and is lost and eliminated via circulation. This can result in potential toxicity from activation of macrophages and the complement system leading to significant inhibition of viral vector entry into the brain (Ikeda *et al*., 1999). The current and efficient mode of viral vector delivery in animal models and human patients is attained by direct stereotaxic injection, which normally involves the use of small amounts of the viral vector to achieve localized expression. The extent of distribution of transgene expression from the

injected site is as important in achieving an optimum therapeutic outcome. The distribution is dependent on the type of viral vector (replicating or nonreplicating), vector dose, the type of therapeutic/cytotoxic transgene encoded, the target site and cells, and principally, the mode of viral vector administration. Studies with lentiviral and AAV vectors have shown predominant infection within neurons (Consiglio *et al*., 2001; Davidson *et al*., 2000), whereas adenoviruses have shown to infect astrocytes and neurons (Smith-Arica *et al*., 2000). Upon viral vector injection, the virus binds to receptors specific to viral capsid proteins. The molecular mechanisms by which viral vectors infect cell types within the brain remains unclear, and further studies on viral uptake and infection will provide a greater insight into the mechanisms of viral vector spread and infection in the brain. Certain elements within transgene sequences have been speculated to have an effect on viral vector spread (Lowenstein and Castro, 2002). Adenoviral vector–mediated expression of β-galactosidase compared to vectors expressing thymidine kinase (tk) gene, derived from the herpes-simplex virus, demonstrated a larger dispersion of tk gene expression in the brain (Dewey *et al*., 1999). Further analysis of the above factors is crucial to study viral vector–based gene expression spread within the brain.

2. Gene therapy approaches to treat CNS diseases: tumors of the CNS

CNS tumors are one of the most serious and frequent forms of cancer affecting both children and adults. Examples of major types of tumors include glioblastoma multiforme (GBM), acoustic neuroma, oligodendroglioma, and pituitary adenomas. The conventional methods of treating brain tumors have been chemotherapy, radiation therapy, and surgical tumor resection. As an alternative approach for brain tumor treatment, gene therapy has progressed into an important therapeutic candidate. The employment of animal brain tumor models, transgenic animals, and established and emerging tumor cell lines all have facilitated to further understand tumor biology, assess, and improve gene therapy and anticancer approaches. Commonly employed animal glioma models are the rat CNS1 model C6 glioma and 9L gliosarcoma, as well as the VM Dk murine astrocytoma and the GL261 murine glioma. The use of transgenic animals is still in its primitive phase (Holland *et al*., 2000; Reilly *et al*., 2000). Major strategies for brain tumor treatment include tumor suppressor gene therapy (Gomez-Manzano *et al*., 1996; Fueyo *et al*., 1998), inactivation of selective oncogenes (Cheney *et al*., 1998), repression of angiogenesis (Kirsch *et al*., 1998), cytokine-mediated enhancement of immune responses (Iwadate *et al*., 2001; Natsume *et al*., 2000), modified dendritic cell–based immunotherapy (Yu *et al*., 2001; Okada *et al*., 2001), antibody-directed prodrug therapy (Napier *et al*., 2000), and virus-mediated enzyme prodrug therapy. An effective tumor treatment strategy is suicide gene therapy in which a cytotoxic gene is selectively expressed in tumor cells, resulting in their death without affecting neighboring normal cells. One example of an enzyme prodrug therapy approach is the Herpes simplex virus (HSV) type 1 thymidine kinase (TK)/glanciclovir (HSV-TK) (Kraiselburd, 1976). Other suicide gene therapy approaches that involve

enzyme-drug complexes include cytosine deaminase/-fluorocytosine (Huber *et al*., 1994) and Carboxypeptidase G2 (Springer *et al*., 1991).

Amalgamation of conventional approaches with gene therapy have successfully been attempted and tested in human clinical trials using retroviral, replication-competent herpes simplex, and adenoviral vectors (Klatzmann *et al*., 1998; Packer *et al*., 2000; Rampling *et al*., 2000; Shand *et al*., 1999; Chiocca *et al*., 2004; Immonen *et al*., 2004). The use of high-capacity adenoviral vectors to selectively deliver and tightly regulate suicide or tumor gene expression would generate a further effective gene therapeutic strategy to the management of brain tumors (Thomas *et al*., 2000).

3. Degenerative diseases of the CNS

3.1. Parkinson's disease gene therapy

Parkinson's disease (PD), though a well-known neurodegenerative disease, its etiology remains unidentified. The disease is not a consequence of a single cause as there is proof of both genetic and environmental components contributing to the development of the disease. The pathological hallmarks are progressive degeneration of dopaminergic neurons in the substantia nigra pars compacta of the basal ganglia. Distinctive cardinal signs of PD include recurring rest tremors, abnormal gait patterns, and unbalanced posture. Gene therapy for PD has made enormous advances in treatment strategies that regenerate and sustain dopaminergic neuronal circuitry and function, and curtailment of cardinal clinical manifestations of the disease.

PD gene therapy studies include prevention of neurodegeneration using lentiviral vector–mediated delivery of glial derived neurotropic factor (GDNF) in MPTP-induced animal models of PD (Kordower *et al*., 2000). Adenoviral vector–mediated delivery of GDNF also produced prolonged protection from dopaminergic neuron degeneration with reduced behavioral symptoms in 6-OHDA-induced animal models of PD (Do Thi *et al*., 2004). Improved HSV-1 amplicons and HSV-1 "disabled" vectors have also demonstrated their effectiveness in repairing this neuronal pathway. HSV-1 amplicon-mediated delivery of tyrosine hydroylase (TH) into the rat striatum reduced behavioral symptoms in 6-OHDA-induced animal models (During *et al*., 1994). Disabled HSV-1-mediated delivery of Bcl-2 to the substantia nigra prevented neuronal degeneration induced in 6-OHDA animals models (Yamada *et al*., 1999). HSV-1 vectors have also demonstrated their capacity to be carried in a retrograde process within the neuronal circuitry from the injection site, providing a suitable approach for achieving targeted delivery of therapeutic genes, which otherwise would be surgically complex (Lilley *et al*., 2001). This has important implications for treatments of neurodegenerative diseases such as PD, as one can precisely deliver therapeutic transgenes by means of neuronal retrograde transport to reach the affected substantia nigra.

Key issues that must be addressed before implementation of neurotrophic factor gene therapy for PD for human clinical trials are (1) the safety of the engineered viral vector and the extent of side effects from the vector dosage given, as

determined from preclinical studies; (2) capacity to control stable and long-term expression of the trophic factor, and (3) the ability to generate negligible levels of immune responses to the elements of the transgene and the viral vector. Regulation of therapeutic transgene expression at the transcriptional level is essential, and can be achieved by switching transgene expression "on" and "off" appropriately.

4. Inherited metabolic and dominant diseases

Common inherited metabolic diseases include phenylketonuria (PKU), cystinuria, and albinism. Examples of dominant inherited diseases include Huntington disease (HD), amyotrophic lateral sclerosis (ALS), and Kennedy's disease. Common aspects of these diseases are that they are adult-onset and progressive, have complex and poorly understood pathophysiology, and induce neuron degeneration and subsequent impairment of motor function. Defined mechanisms by which mutated proteins are leading to neuronal injury in dominant diseases are unclear. Some studies demonstrate possible self-activation mechanisms resulting in the pathogenic process (Zoghbi *et al*., 2000). HD, an autosomal dominant disorder, is a consequence of a trinucleotide CAG expansion at the IT15 locus of chromosome 4 within the Huntington protein whose role is yet unclear. The molecular mechanisms and pathogenesis of the trinucleotide expansion leading to polyglutamine-containing aggregates and subsequent neuronal death are still not clearly known, thus limiting the development of effective therapeutic strategies. The excessive CAG repeats result in degeneration of striatal and cortical neurons in Huntington's and spinal cord in ALS and Kennedy's causing abnormalities in cognitive, motor functions and progressive dementia. There is currently no cure or an effective treatment available for inherited CNS diseases. Gene therapy offers potential hope in providing effective treatment modalities for HD and other inherited CNS disorders, principally involving the use of therapeutic growth factors that are known to enhance neuronal survival neurons. Studies on neurotrophic factor gene therapy using different viral vectors demonstrated their potential in achieving neuronal protection in animal models with HD. AAV vector–mediated delivery of GDNF has been shown to successfully deliver the protein within the striatum providing neuronal and behavioral protection in animal models with HD (McBride *et al*., 2003). First-generation adenoviral vector–mediated delivery of ciliary neurotropic factor (CNTF) and brain derived neurotropic factor (BDNF) also generated widespread neuroprotection in the striatum (Mittoux *et al*., 2002; Bemelmans *et al*., 1999). Using a dual vector approach, lentiviral-mediated tetracycline-regulated delivery of CNTF produced regulated CNTF expression in the striatum using the tet-off regulatory system (Regulier *et al*., 2002). Amyotrophic Lateral Sclerosis (ALS), another neurodegenrative disease, involves advancing degeneration of motor neurons in the spinal cord and the brain, resulting in the patient being paralyzed. A number of hypotheses on the underlying pathogenic mechanisms involved in ALS have been put forward, principally, autoimmunity and excitotoxicity and its potential treatment with I6F1 (Kaspar *et al*., 2003). Further studies at the molecular level will shed light into isolating prominent players in the onset and progression of these diseases.

4.1. *RNA interference strategies to treat inherited dominant diseases*

A promising approach under extensive research for the treatment of dominant inherited diseases is the use of small interfering (si) RNAs. Because dominant diseases commonly arise as a consequence of disease-causing mutated gene sequences, siRNA-based approaches can silence mutated genes responsible for causing the disease. Yet, several dominant disease genes may also encode essential proteins and it will be crucial to inactivate specifically mutant alleles while preserving expression of the nonmutated gene. SiRNA-based inactivation of dominant disease genes emerged from a number of in vitro studies. A pathological hallmark of the inherited dominant familial disease ALS is the occurrence of a point mutation of the *SOD1* gene, which eventually causes symptoms of progressive muscle weakness and degeneration. SiRNA silencing of a mutated version of superoxide dismutase (SOD1) gene resulted in the prevention of cell death from cyclosporin-A toxin insult, in which efficacy and selectivity of allele-specific silencing was achieved using wild type and mutated forms of the HSOD gene (Maxwell *et al*., 2004).

In polyglutamine neurodegenerative disorders such as Machado–Joseph disease and spinocerebellar ataxia type 3 diseases, the characteristic feature is the presence of polyglutamine (polyQ) degeneration, the consequence of CAG-repeat expansions in a particular disease-causing mutated gene. As the normal form of the gene also contains a CAG-repeat, selective targeting to isolate the disease-causing CAG repeat within the expansion chain is difficult. To resolve this problem, allele-specific silencing of disease genes was achieved by using an associated linked single-nucleotide polymorphism (SNP) to generate siRNA that solely inactivated the mutant allele, (Miller *et al*., 2003). The report demonstrated the feasibility of silencing diseased genes differing by a single nucleotide. Other successful siRNA-based therapies include allele-specific silencing of the mutant Torsin A gene for inherited DYT1 dystonia, in which there is a three-nucleotide deletion in the *TOR1A* gene (Gonzalez-Alegre *et al*., 2003), and siRNA-based inhibition specific for mutant SOD1 with single-nucleotide alteration in familial ALS dominant disease (Yokota *et al*., 2004).

Like siRNA, short hairpin RNAs (shRNAs) under the control of RNA polymerase III (pol III) promoters have been shown to induce degradation of messenger RNAs (mRNAs) and subsequently inhibit targeted gene expression (McManus and Sharp, 2002; Brummelkamp *et al*., 2002). Pol III-based shRNA sequences engineered into viral vectors successfully generated RNAi (Brummelkamp *et al*., 2002; Rubinson *et al*., 2003). Using an engineered recombinant AAV vector, Xia *et al*. (2004) reported RNAi suppression of polyglutamine-induced neurodegeneration in a model of spinocerebellar ataxia (SCA1). SCA1 is a dominant polyglutamine expansion disease resulting in a progressive, untreatable neurodegeneration. In a mouse model of SCA1 caused by mutant ataxin-1, intracerebellar injection of AAV vector encoding short hairpin RNAs considerably enhanced motor coordination, sustained cerebellar morphology, and determined characteristic ataxin-1 inclusions in Purkinje cells (Xia *et al*., 2004).

5. CNS gene therapy in the near future

Gene therapy has now been proposed for the treatment of the major groups of brain diseases, including inherited metabolic brain diseases, brain tumors, neurodegenerations, and dominantly inherited diseases. While clinical trials are being pursued, the challenges of sustained and regulatable transgene expression, cytotoxicity, and immune responses remain. It is likely that within a few years gene therapies will become alternative available treatments for brain diseases, which will be offered to patients in addition to classical pharmacological or surgical approaches.

Specialist Review

Cardiovascular gene therapy

Shalini Bhardwaj, Himadri Roy and Seppo Ylä-Herttuala
University of Kuopio, Kuopio, Finland

1. Introduction

Recent advances in gene transfer technologies and better understanding of molecular and genetic bases of cardiovascular disease have made gene therapy an emerging alternative treatment strategy. Promising results have been obtained in animal models of restenosis and vein graft thickening, and limb and cardiac ischemia. Gene therapy for the induction of angiogenesis is based on the concept that myocardial and peripheral ischemia can be improved by stimulating neovessel formation and collateral development from the existing vasculature. Therapeutic vascular growth includes stimulation of angiogenesis, arteriogenesis, and lymphangiogenesis (Ylä-Herttuala and Martin, 2000). Prevention of restenosis can be achieved by inhibiting smooth muscle cell proliferation, migration, matrix synthesis, remodeling, and thrombosis.

Gene therapy has the potential advantage of enabling gene expression for a sufficiently long period, at an adequate concentration to stimulate effective therapeutic response from a single administration. However, full potential of this therapy can be achieved only after further development of gene transfer technology and selection of effective treatment genes.

2. Choice of angiogenic factors

Angiogenic signals are mediated by a number of growth factors and cytokines. The endothelial specific growth factors include members of the vascular endothelial growth factor (VEGF) family of proteins and the angiopoietin (Ang) family. Different members of the VEGF family act as key regulators of endothelial cell function, controlling vasculogenesis, angiogenesis, vascular permeability, and endothelial cell survival (Ferrara and Davis-Smyth, 1997). Other factors that promote angiogenesis are fibroblast growth factors (FGFs), hepatocyte growth factor (HGF), epherins, platelet derived growth factors (PDGFs), and hypoxia-inducible factor-1 (HIF-1). Vessel survival is dependent on VEGF and other exogenous survival factors. Angs act during remodeling of vascular plexus and a combination therapy with VEGF and Ang-1 may produce more stable vessels.

Another important aspect is induction of angiogenesis by angiogenic master switch genes, such as HIF-1α and HGF, which stimulate multiple neovascularization cascades.

2.1. Vascular endothelial growth factors (VEGFs)

VEGF family comprises of six members, VEGF-A, -B, -C, -D, -E, and placental growth factor (PIGF), which differ in their molecular mass and biological properties. The mechanism of action is through tyrosine kinase receptors, VEGFR-1, VEGFR-2, and VEGFR-3. VEGF-A is known to play a crucial role in angiogenesis and vasculogenesis and is a ligand for VEGFR-1 and VEGFR-2 (Ferrara, 2001). VEGF-A promotes increased microvascular permeability and fibrin deposition that may be responsible for enhanced migration of endothelial cells in extracellular matrix. It supports the survival of endothelial cells by expressing antiapoptotic proteins in these cells. In phase I and II clinical trials, VEGF-A plasmid/liposome or adenovirus vector has been used for coronary artery disease (CAD), in-stent restenosis, and peripheral artery occlusive disease. Vascular endothelial growth factor B (VEGF-B) is structurally related to VEGF-A and binds only to VEGFR-1 (Olofsson *et al*., 1998). VEGF-B is a very weak mitogen when tested in mammalian cells. The receptors for VEGF-B are located on endothelial cells; thereby, it is more likely to act in a paracrine manner.

Expression of VEGF-C occurs during early embryonic development before the emergence of lymphatics, which is suggestive of its role in vasculogenesis and angiogenesis. VEGF-D has angiogenic and lymphangiogenic potentials (Bhardwaj *et al*., 2003; Rissanen *et al*., 2003). Both VEGF-C and VEGF-D act through VEGFR-2 and VEGFR-3 (Hamada *et al*., 2000; Achen, 1998). Biological activity of VEGF-C and -D depends on proteolytic cleavage. VEGF-E was discovered in the genome of the Orf virus, and signaling through VEGFR-2 and neuropilin receptor (NRP-1) causes endothelial cell mitogenesis. PIGF-1 binds specifically to VEGFR-1 and is a nonheparin binding protein. PIGF-2 is a heparin binding protein that binds to VEGFR-1 and NRP-1. VEGF and PIGF form heterodimers have been found to bind to VEGFR-2. High concentration of PIGF saturates VEGFR-1 binding sites and augments the action of VEGF, which then acts through VEGFR-2. PIGF is chemotactic to endothelial cells and monocytes.

2.2. Angiopoietins (Angs)

Angs are a group of growth factors that affect the growth of endothelial cells. They bind to the receptor Tie2 (tyrosine kinase with immunoglobulin and epidermal growth factor homology domain) (Sato *et al*., 1995). Ang1/Tie-2 along with VEGF/VEGFR-2 is critical for mobilization and recruitment of hemopoietic stem cells and the circulation of endothelial cell precursors. Property of Ang-1 to reduce vascular leakage and inflammation might prove beneficial in vascular gene therapy. Ang-2 is an antagonist for Ang-1 and is probably needed for vascular remodeling.

2.3. Hypoxia-inducible factor-1 (HIF-1)

HIF-1 is a transcription factor that acts as a regulator of oxygen homeostasis. It acts as a transcriptional activator of VEGF gene. A cellular enzyme HIF-1α prolyl hydrolase (HIF-PH) probably serves as a cellular oxygen sensor. HIF-1α administered via gene transfer induces expression of VEGF, which leads to therapeutic neovascularization of ischemic tissues. This property of HIF-1 has been used for promoting therapeutic angiogenesis.

2.4. Platelet-derived growth factors (PDGFs)

The family of PDGFs currently compromises of four members, PDGF-A, -B, -C, and -D, which bind to receptors PDGFR-α and PDGFR-β. They are major mitogens for fibroblasts, smooth muscle cells, and several other cell types. PDGF-A and PDGF-B form homo and heterodimers with their tyrosine kinase receptors, whereas PDGF-C and PDGF-D form apparently only homodimers. Increased PDGF activity has been implicated in several pathological conditions in adults, including atherosclerosis, restenosis, fibrosis, and tumorigenesis. PDGF receptor (PDGFR) inhibition is known to reduce restenosis in experimental animals.

2.5. Fibroblast growth factors (FGFs)

FGFs are known to stimulate cell migration and cell mitosis and affect cellular senescence. FGF signaling contributes to multiple, distinct steps in vessel formation. These steps include proliferation and differentiation of Flk1-positive hemangioblastic precursor cells from mesoderm, assembly of endothelial cells during vasculogenesis, and sprouting angiogenesis. FGFs can regulate vascular morphogenesis by acting either directly through FGFRs or indirectly by inducing other angiogenic factors like VEGFs. FGF is produced by angiogenic tissue, and it can be released to stimulate endothelial cells, smooth muscle cells, and pericytes. Thus, FGFs might be responsible for the maturation of blood vessels. Adenoviral mediated FGF-4 gene delivery has been used in Phase II clinical trials for peripheral artery occlusive disease and coronary artery disease.

2.6. Hepatocyte growth factor (HGF)

Hepatocyte growth factor stimulates proliferation and migration of endothelial cells through *c-Met* (a transmembrane tyrosine kinase) receptor present on endothelial cells and some other cell types including smooth muscle cells and pericytes. Overexpression of HGF in the skin increases granulation tissue formation, angiogenesis, and VEGF levels. It has been used to promote therapeutic angiogenesis in animal models and in a clinical trial.

2.7. Ephrins (Eph)

The Eph family of receptor tyrosine kinases is the largest known family of receptor tyrosine kinases (RTKs) identified so far. Expression of ephrin ligands may be induced by growth factors and cytokines in various cell types. Ligands of EphB family induce capillary sprouting in vitro. Expression of ephrin-B2 and its cognate EphB receptors in mesenchymal cells adjacent to vascular endothelial cells suggests an EphB/ephrin-B2 interaction at endothelial-mesenchymal contact zones. Ephrin-A1 is expressed at sites of vascular development. The Eph receptor family represents a new class of receptor tyrosine kinases, and their role in angiogenesis is yet to be defined.

2.8. Risks associated with angiogenic gene therapy

Certain risks are associated with therapeutic angiogenesis and include formation of hemangiomas or vascularization of tumors, neovascularization in atherosclerotic lesions leading to plaque rupture, development of nonfunctional vessels, and edema. Increasing the tissue specificity of the gene constructs and promoters and regulating the transgene expression should minimize these risks.

3. Targeted gene delivery systems

The efficacy and safety of gene therapy also depends on targeting genes to particular cells and effectively controlling their expression. Developing vectors with defined cell-type trophism or using cell-specific promoters and regulatory elements can produce better targeting (Harris and Lemoine, 1996).

Receptor-mediated targeting is based on receptor ligand interaction. Modified vectors have been prepared that target binding to alternative attachment receptors, improving vector specificity. Adenoviruses are widely used vectors for gene transfer to dividing and nondividing cells (*see* Article 96, **Adenovirus vectors**, Volume 2). However, they have broad cell tropism and transgene expression is often detected in various ectopic organs. Novel adenoviruses targeted to vascular wall have been developed. They include matrix metalloproteinase-2 and -9 (MMP-2 and -9) targeted TIMP-1 encoding adenoviruses, $\alpha\nu$ integrin targeted human interleukin-2 encoding adenoviruses, and endothelial cell targeted adenoviruses. Additionally, blocking of (Coxsackie and adenovirus) CAR receptors may lead to targeted expression by adenoviral vectors (Kibbe *et al*., 2000).

In transcriptional targeting, tissue or cell type–specific promoters and regulatory elements are used to restrict expression in nontarget tissues. Endothelial specific promoters include *fms-like* tyrosine kinase-1 (FLT-1), intercellular adhesion molecule-2 (ICAM-2), von Willebrand factor, and Tie promoters. The SM22alfa promoter restricts transgene expression exclusively to smooth muscle cells after adenovirus-mediated gene transfer to arterial wall. Along with the use of viral promoters in cardiovascular gene transfer, vectors containing inducible promoters are now being used to regulate gene expression and to optimize therapeutic

effect. An example of inducible promoters is *Escherichia coli* tetracycline responsive element *tet*, which activates transcription of the transgene only in the presence of tetracycline. Another strategy is the use of endogenous stimuli to regulate transgene expression. Examples of this approach are vectors containing transcription regulatory elements sensitive to hypoxia, which can be effectively used for the regulation of transgene expression in ischemic tissues. The hypoxia response element (HRE) is introduced into an expression cassette and gene expression is activated by HIF-1 under ischemic conditions (Dachs *et al*., 1997).

4. Potential therapeutic targets

4.1. Atherosclerotic vascular disease and thrombosis

Atherosclerosis is characterized by deposition of atheromas or plaques in the inner layers of arteries. These plaques can ultimately occlude an artery, or an unstable plaque can result in thromboembolic episodes. Complex etiology of atherosclerosis makes the use of a single or local gene transfer for its prevention or treatment a controversial issue. But several genetic disorders with a single gene defect, which predispose to the development of atherosclerosis, can be treated with gene therapy. In cases of low-density lipoprotein (LDL) receptor deficiency, LDL receptor and very low density lipoprotein (VLDL) receptor gene transfers to liver may prove beneficial. Lecithin cholesterol acyl transferase (LCAT) or lipid transfer protein gene transfer can be used to treat certain dyslipoproteinemias. It is possible to inhibit the elevated levels of atherogenic apolipoprotein (apo) B100 by apobec-1 gene transfer, which is a catalytic subunit of apoB editing enzyme. ApoA1 gene transfer that promotes reverse cholesterol transport might be used to treat apoA1 deficient patients. ApoE gene transfer might be useful for decreasing lipoprotein levels in the treatment of Type III Hyperlipoproteinemia. Lipoprotein lipase and hepatic lipase gene transfers could benefit patients having deficiency of these enzymes. Class A soluble scavenger receptor gene transfer could decrease lipid accumulation in macrophages and class B soluble scavenger receptors can alter high-density lipoprotein (HDL) levels. Decreased nitric oxide (NO) bioavailability probably results in endothelial dysfunction, occurring in early atherosclerosis. It could be corrected by using endothelial nitric oxide synthase (eNOS) and VEGF genes. In advanced cases of atherosclerosis, however, an increased NO production may not be useful. Rho family GTPases participates in the regulation of actin cytoskeleton and cell adhesion. Inhibiting Rho kinase (RhoK) by dominant negative RhoK gene transfer decreases atherosclerosis. Overexpression of antioxidant enzymes like superoxide dysmutase (SOD) also helps in decreasing atherosclerosis. It has been seen that Interleukin-10 (IL10) and platelet activating factor acetyl hydrolase (PAF-AH) gene transfers decrease atherosclerosis probably via their antiinflammatory effects. Rupture of an unstable plaque and subsequent thrombosis in an atherosclerotic artery might precipitate an acute ischemic episode. TIMP gene transfer may prove useful to stabilize unstable plaques. Other gene transfers used to decrease thrombotic episodes in animal models include cyclooxygenase, hirudin, thrombomodulin, tissue plasminogen activator, and tissue factor pathway inhibitor.

4.2. Coronary artery disease (CAD) and peripheral artery disease (PAD)

Coronary artery occlusion due to atherosclerosis can result in myocardial ischemia. Angiogenic gene therapy is aimed at promoting new blood vessel formation in ischemic myocardium, thereby improving cardiac perfusion, exercise tolerance, and quality of life. Therapeutic angiogenesis using VEGF, FGF, HGF, and HIF-1α has proved beneficial in many animal models. Improvement in exercise tolerance was reported after adenovirus-mediated VEGF gene transfer to ischemic myocardium. Targeted delivery of angiogenic growth factors using sophisticated delivery systems like NOGA catheters might further improve chances of rescuing ischemic myocardium.

In PAD, there is decreased blood supply to the limbs because of arterial obstruction and vasoconstriction. Many of these patients suffer from disabling symptoms like severe ischemic rest pain, and amputation is often required to alleviate suffering. Therapeutic angiogenesis using angiogenic growth factors has been recently used to treat critical limb ischemia. VEGF, FGF, and HGF gene transfers have been used to promote development of collateral blood vessels in animal models and clinical trials. Angiopoietins can also possibly enhance the maturity of new vessels formed after VEGF gene therapy. Other cytokines like Monocyte chemotactic protein-1 (MCP-1) and PDGFs can also promote angiogenesis indirectly.

4.3. Arterial restenosis and vein graft disease

Maladaptive response to injury can result in occlusion of an artery as seen after balloon angioplasty, stenting, or in bypass vein graft. Restenosis is defined as a diameter stenosis of 50% at follow up. Restenosis occurs in 10–30% of patients after balloon angioplasty and stenting. Multiple factors including smooth muscle cell proliferation, matrix accumulation, remodeling, thrombosis, and platelets and leukocyte adhesion are involved in the development of arterial restenosis after angioplasty, stenting, and in vein graft disease. Various gene therapy strategies have been employed to decrease cellular proliferation. These include antisense oligonucleotides and ribozymes against *c-myb, c-myc, cdc-2, cdk-2, ras, bcl-x*, or decoy constructs against transcription factors such as E2F and NFkB. Cell cycle inhibitors like nonphosphorylated retinoblastoma gene, p21, p27, p53, and *gax* can decrease cellular proliferation and neointima formation. Similarly, (Herpes Simplex Virus-Thymidine Kinase) HSV-TK, cytosine deaminase, preprocecropine A, and *fas* ligand gene transfers have been shown to decrease cellular proliferation and smooth muscle cell migration in the blood vessels. Transfer of VEGF and HGF genes to vessel wall has been shown to decrease neointima formation, possibly by enhancing endothelial repair. It has been hypothesized that rapid regeneration of endothelial cells results in secretion of antiproliferative substances like nitric oxide, C-type natriuretic peptide, and prostacyclin I_2. Gene transfer of TIMP-1, nitric oxide synthtase, and dominant negative Rho kinase has resulted in decreased neointima formation in animal models. Inhibition of thrombosis by recombinant hirudin (inhibitor of thrombin) gene transfer resulted in decreased neointima formation

in animal models. Only a limited number of gene therapy clinical trials have been conducted for restenosis and vein graft disease. Ex vivo gene transfer of E2F decoy in vein grafts has been successful in decreasing graft failure rate in human trials. Other clinical trials for gene therapy in restenosis and vein graft disease have so far been inconclusive.

4.4. Systemic hypertension

Essential hypertension is a progressive disease characterized by chronically elevated blood pressure of unknown etiology (*see* Article 63, **Hypertension genetics: under pressure**, Volume 2). Multifactor and intricate etiology of systemic hypertension has led to the question of feasibility of gene therapy in hypertension. But it has been shown that altering certain mediators by gene therapy can result in effective lowering of systemic blood pressure. Argument in favor of gene therapy for hypertension has been that a single gene transfer might be able to control systemic hypertension for a long term, thereby improving patient compliance. One approach has been to transfer genes, which increase vasodilator proteins like tissue kallikrein, atrial natriuretic peptide (ANP), adrenomedullin, and eNOS. Another approach has been to decrease the vasoconstrictor proteins. Antisense oligonucleotides and DNA have been used against β-adrenoreceptors, angiotensin converting enzyme (ACE), angiotensin type-1 receptors, angiotensin gene activating element, thyrotropin releasing hormone (TRH) and TRH receptor, carboxypeptidase y, *c-fos,* and CYP4A1. Although promising results have been obtained in animal models for hypertension, no clinical trial for gene therapy in systemic hypertension has yet taken place.

4.5. Pulmonary hypertension

Pulmonary hypertension is characterized by progressively increasing pulmonary artery pressure. Primary pulmonary hypertension (PPH) is a disease of unknown etiology, while secondary pulmonary hypertension results from diseases like collagen vascular disease, congenital heart disease, chronic thrombotic/ and or embolic disease, chronic obstructive pulmonary disease, chronic hypoxia, and certain drugs. Mutations in BMPR-II (encoding bone morphogenetic protein receptor II) have been reported in many cases of sporadic cases of PPH. It is usually a progressive and fatal disease. Gene therapy to decrease cellular proliferation and vasospasm in pulmonary vessels has so far been limited to animal studies.

MCP-1, Prepro-calcitonin gene related peptide, atrial natriuretic peptide, eNOS, prostacyclin synthtase and VEGF gene transfers have been used with varying degree of success in animal models for pulmonary hypertension.

4.6. Congestive cardiac failure and cardiomyopathies

Alterations in myocardial β-adrenergic receptor system and intracellular calcium signaling play a crucial role in the pathophysiology of heart failure. Ability to genetically manipulate beta-adrenergic receptor system and calcium signaling might prove beneficial in the management of chronic congestive cardiac failure of primary

Table 1 Therapeutic genes and their disease targets

Treatment target	Therapeutic genes
Atherosclerosis	VLDL receptor, LDL receptor, apoE, apoA-1, lipoprotein lipase, hepatic lipase, LCAT, apoB, lipid transfer proteins, Lp(a) inhibition, soluble scavenger-receptor decoy, soluble VCAM or ICAM, SOD, IL-10, PAF-AH
Thrombosis	Hirudin, tPA, thrombomodulin, TFPI, COX
Unstable plaque	TIMPs, COX, soluble VCAM
Restenosis and vein graft failure	VEGF-A, C, eNOS, iNOS, TIMPs, TK, COX, gax, CyA, p53, Rb, sdi-1, fas ligand, p16, p21, p27, NFkB and E2F decoys, cdk-2, cdc-2, c-myb, c-myc, ras, bcl, Gbg, PCNA antisense oligonucleotides, ribozimes, cecropine A, blocking PDGF or TGF-b expression or their receptors
Systemic hypertension	Tissue kallikrein, ANP, adrenomedullin, eNOS, Adrenoreceptor, ACE, angiotensin II type-1 receptor, angiotensin gene activating element, TRH receptor, TRH, carboxypeptidase y, c-fos, CYP4A1 antisense oligonucleotides
Therapeutic angiogenesis	VEGF-A, -B, -C, -D, -E, PlGF-1, FGF-1, -2, -4, -5, Angiopoetin-1, -2, HGF, MCP-1, PDGF, eNOS, iNOS
Pulmonary hypertension	Prepro-calcitonin gene related peptide, ANP, eNOS, prostacyclin syntase, VEGF-A

VEGF: Vascular endothelial growth factor; PIGF: Placental growth factor; HGF: Hepatocyte growth factor; FGF: Fibroblast growth factor; MCP-1: Monocyte chemotactic protein-1; PDGF: Platelet-derived growth factor; NOS: Nitricoxide synthase; ANP: Atrial natriuretic peptide; TIMP: Tissue inhibitor of metalloproteinase; TK: Thymidine kinase; CyA: Cytosine deaminase; Rb: Retinoblastoma gene; sdi-1: Senescent cell-derived inhibitor-1; PCNA: Proliferating cell nuclear antigen; TGF- β: Transforming growth factor β; VCAM: Vascular-cell adhesion molecule; ICAM: Intercellular adhesion molecule; LCAT: Lecithin cholesterol acyl transferase; COX: Cyclooxygenase; NFkB: Nuclear factor kappa B; ACE: Angiotensin converting enzyme; TRH: Thyrotropin releasing hormone; SOD: Super oxide dysmutase; IL-10: Interleukin-10; PAF-AH: Platelet activating factor acetyl hydrolase; TFPI: Tissue factor pathway inhibitor; tPA: Tissue plasminogen activator.

myocardial origin, where conventional drug therapy is often inadequate. HGF gene transfer that has an antifibrosis and antiapoptosis action in the myocardium was beneficial in an animal model of cardiomyopathy with heart failure. Recent genetic studies have revealed that mutations in genes for cardiac sarcomere components lead to dilated cardiomyopathy. Mutations in the Z-line region of titin were found along with decreased binding affinities of titin to Z-line proteins. Gene therapy directed at correcting defective sarcomeric proteins may prove beneficial in cases of familial cardiomyopathy.

Various therapeutic genes and their disease targets are listed in Table 1.

5. Delivery systems for cardiovascular gene transfer

Selection of an appropriate system results in efficient expression of the therapeutic gene. Gene delivery to the cardiovascular system could be local, regional, and systemic. Local gene transfer is required in cases of atherosclerotic lesions, vein graft, ischemic conditions of myocardium or skeletal muscle, regional as in the case of pulmonary hypertension or systemic as in atherosclerosis and hypertension. Perivascular collars or sheaths, needle injection catheters, and biodegradable gels can be used for delivering the vectors to adventitia (Laitinen *et al*., 1997; Laitinen and Ylä-Herttuala, 1998). When specific physical or biological targeting methods are available, they usually improve transgene expression (Ylä-Herttuala and Alitalo,

2003). Ultrasound, microbubbles and electronic pulses can be used to enhance gene transfer efficiency. Local delivery to small arterioles and capillaries can also be achieved by using coated biodegradable microspheres.

Successful transfection of smooth muscle cells in media could be achieved by high-pressure intra luminal gene delivery. Disruption of intima and internal elastic lamina by balloon angioplasty and subsequent delivery of the vector by infusion catheter results in transfection of medial SMC. Coated stents and hydrogel coated balloon catheters are also useful for delivering vectors to endothelial cells or medial smooth muscle cells (Riessen *et al*., 1993). Different types of catheters have been developed for the delivery of vectors to blood vessels, such as double, gel coated, porous channel balloon and dispatch catheters.

Vector delivery to ischemic myocardium for CAD has been achieved using intramyocardial injections via thoracotomy and intracoronary injections (Hedman *et al*., 2003). A recent introduction to myocardial gene transfer is nonfluoroscopic catheter-based electromechanical mapping system (NOGA, Biosense Webster, Inc). NOGA system assesses the reduction in electrical voltage and mechanical activity in ischemic myocardium, thereby differentiating it from healthy tissue. Pericardial delivery of the vectors can also be useful for transferring genes to myocardium and coronary arteries. Gene delivery for the treatment of peripheral arterial disease (PAD) can be done by the use of direct intramuscular injections (Isner *et al*., 1998), infusion–perfusion catheters, and hydrogel coated balloon catheters.

6. Issues in clinical trial design

The field of therapeutic angiogenesis for CAD is fast growing from basic and preclinical investigations to clinical trials although many new issues need to be addressed. These include a deep understanding of the biology of angiogenesis, selection of appropriate patient populations for clinical trials, choice of therapeutic end points for curative or palliative purposes, choice of therapeutic strategy, route of administration, and the side effect profile (Isner *et al*., 2001).

The induction of arteriogenesis is clinically more relevant in maintaining the cardiac function and patient survival than angiogenesis as demonstrated by the fact that myocardial infarction patients are less likely to develop ventricular aneurysms and show improved survival, if they have collateral arteries. Patient selection is another important feature, both with respect to age and genetic background. There is age dependent impairment of VEGF expression at least in part caused by impaired induction of HIF-1 activity in response to ischemia or hypoxia. Combination therapies using different growth factors according to their role in the initiation of growth and maintenance of blood vessels are needed to ensure long-term viability of these vessels. An alternative to this is the use of “angiogenic master switch” genes like HIF-1α that is capable of initiating multiple neovascularization cascades.

Presently, most gene transfer studies in cardiovascular gene therapy are preclinical, although a number of high profile vascular gene therapy clinical trials are in progress. The most important targets for cardiovascular gene therapy are CAD and PAD. The clinical trials for cardiovascular gene therapy are summarized in Table 2A and 2B.

Table 2 Clinical trials in cardiovascular gene therapy

(A) Trials for therapeutic angiogenesis

Investigator	Location	Disease	Delivery route	No. of patients	Treatment	Phase	Vector
Isner *et al*.	St. Elizabeth's Medical Center, Boston, MA, USA	Peripheral artery occlusive disease	Intramuscular injection	6	VEGF-A	I	Plasmid
Baumgartner *et al*.	St. Elizabeth's Medical center, Boston, MA, USA	Peripheral artery occlusive disease	Intramuscular injection	9	VEGF-A	I	Plasmid
Berlex Schering AG	Multicenter trial, Europe	Peripheral artery occlusive disease	Intramuscular injection	[a]	FGF-4	II	Adenovirus
Symes *et al*. (1999)	St. Elizabeth's Medical Center, Boston, MA, USA	Severe coronary artery disease	Intramyocardial injection via thoracotomy	20	VEGF-A	I	Plasmid
Rosengart *et al*.	Cornell Medical Center, New York, USA	Coronary artery disease	Intramyocardial injection during bypass surgery or minithoracotomy	21	VEGF-A	I	Adenovirus
Grines *et al*. (2002) Berlex Laboratories	Multicenter trial, USA	Coronary artery disease	Intracoronary injection	131	FGF-4	II	Adenovirus
Kastrup *et al*.	Multicenter trial, Europe	Coronary artery disease	Intramyocardial injections NOGA	48[a]	VEGF-A	II	Plasmid
Hedman *et al*.	Kuopio University Central Hospital, Kuopio, Finland	Coronary artery disease, in-stent restenosis	Infusion–perfusion catheter after angioplasty and stenting	103	VEGF-A	II	Plasmid/ liposome or adenovirus
Mäkinen *et al*. (2002)	Kuopio University Central Hospital, Kuopio, Finland	II Peripheral artery occlusive disease	Infusion–perfusion catheter after angioplasty	54	VEGF-A	II	Plasmid/liposome or adenovirus

[a]Ongoing recruitment.

(B) Trials for restenosis and vein graft failure

Investigator	Location	Disease	Delivery route	No. of patients	Treatment	Phase	Vector
Laitinen *et al*. (2000)	Kuopio University Central Hospital, Kuopio, Finland	Coronanry artery disease, restenosis	Infusion–perfusion catheter after angioplasty	10	VEGF-A	I	Plasmid/liposome
Mann *et al*.	Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA	Vein graft stenosis, infrainguinal bypass surgery	Pressure mediated ex vivo delivery	41	E2F Decoy	II	Oligonucleotide
Grube *et al*.	Multicenter trial	Coronary vein graft stenosis	Pressure mediated ex vivo delivery	200	E2F Decoy	II	Oligonucleotide
Kutryk *et al*.	University Hospital Dijkzigt, Rotterdam, Netherlands	Coronary artery disease, in-stent restenosis	Catheter after stenting	85	c-myc antisense	II	Oligonucleotide
Cardion AG	Multicenter trial	Coronary artery disease, in-stent restenosis	Infiltrator catheter af ter stenting	[a]	iNOS	I	Plasmid/lipoplex

[a] Ongoing recruitment

Short Specialist Review

Artificial self-assembling systems for gene therapy

Pierre Lehn
Hôpital Robert Debré, Paris, France

1. Introduction

Nonviral gene delivery systems are nowadays widely investigated as an alternative approach to recombinant viruses for gene therapy studies. Indeed, although nonviral vectors still suffer from a limited efficiency, they are free from a number of inconveniences associated with the use of viruses. One may consider nonviral systems to include all physical and chemical methods for gene transfer. Although combining physical techniques (such as electroporation, gene gun, hydrodynamic pressure, and ultrasound) has recently improved gene transfection using naked DNA, we will herein focus on chemical gene transfer systems that can be viewed as virus-like systems, as all steps involved in virus-mediated gene transduction are of chemical nature. Thus, we will describe the main characteristics of the current chemical vectors and outline the cellular and molecular barriers still limiting their transfection activity. In this forward-looking chapter, we will also discuss strategies to improve in vivo gene delivery, in particular, the development of sophisticated modular systems constituting true "artificial viruses".

2. Nonviral vectors versus recombinant viruses

The use of an efficient and safe gene delivery system is an obvious prerequisite for successful gene therapy. Viral vectors have been shown to be particularly efficient for gene transfer. Indeed, viruses are smart nucleic acid–containing supramolecular assemblies that have been tailored by evolution for transferring their genes from one cell to another. Accordingly, several viral vector systems have been developed (retroviruses, adenoviruses . . .) over the last decade. All of these viral systems rely on the generation of replication-defective recombinant viral particles by genetically engineered "producer" cells. It is therefore no surprise that viral vectors suffer from drawbacks resulting from their biological nature, in particular, safety concerns, immunogenicity issues, and practical issues relating to large-scale production and quality control. These inherent limitations of viral vectors have led to the development of an alternative de novo approach in which synthetic organic

molecules are used as DNA carriers (Lehn *et al*., 1998). Such artificial vectors (termed nonviral vectors) are indeed free of the infection risks of recombinant viruses as they are well-characterized compounds obtained in the test tube via chemical synthesis. Other advantages of nonviral vectors include their probable low immunogenicity, ease of large-scale production, and cost-effectiveness. Further, in contrast to viral vectors in which capsids have a predetermined size, there is no (upper, lower) size limit for the DNA to be transferred by chemical vectors, as the vector/DNA complexes are formed via a self-assembling process in the test tube. Thus, synthetic vectors allow the transfer of not only eukaryotic expression cassettes for cDNAs but also large genomic constructs as well as short nucleic acid sequences (Aissaoui *et al*., 2002).

3. Current vectors: DNA condensing agents

The current nonviral vectors belong to one of two main categories: cationic liposomes/micelles or cationic polymers (Kabanov *et al*., 1998; Huang *et al*., 1999). Spontaneous formation of self-assembled nanometric vector/DNA complexes is in both cases due to electrostatic interactions between the positively charged chemical vector and the negatively charged DNA. Lipoplex is the name given to the complexes formed between cationic lipids and DNA, whereas the complexes formed by cationic polymers are termed polyplexes. The DNA entrapped in these complexes is then protected from degradation by nucleases. It is generally agreed that use of an excess of cationic vector yields DNA complexes with a net positive charge whose binding to negative cell surface residues (such as proteoglycans) leads to nonspecific, electrostatic-driven endocytosis. Once inside the cell, the DNA has, however, still to perform several steps before being transcribed in the nucleus: escape from the endosome into the cytoplasm (to avoid degradation in the lysosome), trafficking to the perinuclear region, and finally passage across the nuclear membrane (Zabner *et al*., 1995).

Cationic lipids are especially attractive as they can be prepared with relative ease and extensively characterized. All cationic lipids are positively charged amphiphiles containing three functional domains: (1) a polar hydrophilic head group, which is positively charged, generally via protonation of one (monovalent lipid) or several (multivalent reagents) amino groups; (2) a linker whose nature and length impact on the stability and biodegradability (and consequently on the toxicity) of the vector; (3) a hydrophobic moiety composed of either two alkyl chains (saturated or unsaturated) or cholesterol. The first use of a monovalent cationic lipid for in vitro gene transfection into cultured cells was reported in 1987 (Felgner *et al*., 1987). A multivalent lipopolyamine soon followed, whereas use of cholesterol as the hydrophobic anchor was subsequently validated (Miller, 1998). Since this initial “proof of principle” period, many other cationic lipids have been synthesized (often on a basis of trial and error) in order to develop better vectors (Miller, 1998; Martin *et al*., 2003). Modifications have been made in the design of each of the fundamental constituent parts of a cationic lipid. First, the choice of head group has expended into the use of natural architectures and functional groups with recognized DNA binding modes. For example, the transfection efficiency of

cationic cholesterol derivatives characterized by a head group with guanidinium functions or natural aminoglycoside structures has been reported by us (Vigneron *et al*., 1996; Belmont *et al*., 2002). Second, modifications of the hydrophobic portion revealed that optimal vector design was also highly dependent on this moiety. Here, because of its rigidity, cholesterol has been used when lipoplexes with a high degree of stability were required as for aerosol delivery. Finally, stable linking of the hydrophilic and hydrophobic portions is commonly achieved using a variety of chemical bonds (carbamate, amide, ester, ether). Of note, cationic lipids are often formulated as liposomes with the neutral colipid DOPE (dioleoyl phosphatidylethanolamine), as DOPE is thought to have fusogenic properties that may enhance endosomal escape of the DNA to the cytoplasm (Miller, 1998; Martin *et al*., 2003).

Several cationic polymers have been reported to form complexes with DNA and promote gene transfection. The linear polymer poly-L-Lysine (pLL) was the first cationic polymer to be used for gene delivery (Wagner, 1998). Its efficiency was, however, found to be low in the absence of additional agents facilitating cellular uptake or endosomal release. Cellular uptake could be improved by conjugation to the carrier of a variety of ligands (such as transferrin, antibodies, RGD tripeptide motifs ...) specific for receptors on the target cells. Endosomal escape was enhanced via the use of lysosomotropic agents (chloroquine), defective virus particles, and fusogenic peptides. Next, polyamidoamine (PAMAM) dendrimers are spherical macromolecules bearing a large number of amine groups on their surface which were also tested for DNA delivery. In contrast to intact dendrimers, degraded or fractured PAMAM dendrimers mediated very efficient gene transfection in vitro (Tang *et al*., 1996). Polyethylenimine (PEI) is a recent but impressive addition to the list (Boussif *et al*., 1995). PEI has a very high charge density potential, as every third atom is an amino nitrogen atom. However, at physiological pH, only a fraction of these amino groups are protonated. Thus, it has been proposed that the high gene transfer efficiency of PEI was due to its strong buffering capacity. Indeed, the capacity of PEI to capture protons at the acidic pH of the endosome may cause osmotic swelling and subsequent endosome disruption with release of the DNA ("proton sponge" mechanism) (Kichler *et al*., 1999). Finally, it is noteworthy that efficient gene transfection has also been mediated by several other cationic polymers and block copolymers and, in the particular case of the muscle, even by nonionic polymers and copolymers (Kabanov *et al*., 1998; Kabanov *et al*., 2002).

4. Clinical gene therapy trials

Encouraging data from a variety of animal studies have provided a reasonable basis for subsequent clinical trials in man (Kabanov *et al*., 1998; Huang *et al*., 1999). For example, local intratumoral or regional (intracavitary) gene therapy with various types of lipoplexes showed a significant antitumor effect. Other studies demonstrated that nonviral vectors mediated efficient transfection of the airway epithelial cells. Accordingly, in the first clinical gene therapy trials with cationic lipids, the lipoplexes were applied via in situ administration such as instillation

into the airways (of cystic fibrosis patients) or direct intratumoral injection (Hersh and Stopeck, 1998; Davies *et al*., 2001; see also the interactive database of The Journal of Gene Medicine clinical trials website at **http://www.wiley.co.uk/genmed/clinical**). These clinical trials basically showed encouraging safety and biological activity data, but they also clearly emphasized that more efficient systems were required.

5. Future directions: toward multifunctional systems

It is thus nowadays agreed that more efficacious nonviral vectors need to be developed before gene therapy can be regarded as a viable therapy. As such improved systems need to be capable of overcoming the multiple barriers encountered in vivo, most research efforts focus at present on providing the vector/DNA complexes with the various functions required for surmounting these barriers: (1) stabilization of the lipoplexes/polyplexes in the extracellular medium (via "stealth technology" involving pegylation); (2) equipment of the DNA complexes with receptor-specific ligands (sugar residues, folate ...) for targeted transfection; (3) enhancement of endosomal escape and "triggered" decomplexation of the DNA via incorporation of functional groups sensitive to cellular stimuli, such as the decrease in pH along the endosomal/lysosomal pathway or the cytoplasmic redox potential; (4) facilitated trafficking to the perinuclear region (probably along the microtubule network); and (5) inclusion of ligands (such as nuclear localization signals, steroids ...) for nuclear uptake (Miller, 1998; Yonemitsu *et al*., 1998; Martin *et al*., 2003; Kichler, 2004; Wagner, 2004). The future will require the difficult task of incorporating all the functions described above into a single system. In addition, the different functional components need to be capable of working in a chronological order to avoid unwanted interreactivity of the individual functions (Lehn *et al*., 1998). Finally, present research also focuses on the development of improved gene constructs. Indeed, nonviral vectors are nowadays generally used to transfer plasmids (containing eukaryotic expression cassettes) that lead to transient expression of the transgene. Here, research efforts aim, in particular, at decreasing the immune response to the unmethylated CpG motifs in the plasmid DNA and designing self-replicating or integrating plasmid expression systems to increase the duration of transgene expression (Aissaoui *et al*., 2002).

6. Conclusions

Over the last decade, a variety of nonviral gene delivery systems have been developed and shown to mediate efficient gene transfection in vitro. Their in vivo efficiency was, however, found to be much less satisfactory. The goal of current research is thus to develop improved vectors for efficient and safe in vivo gene delivery. The design of such improved vectors can nowadays be based on a better understanding of the various barriers encountered by the DNA complexes while trafficking from the extracellular medium to the nucleus of the target cells. Accordingly, improved vectors may consist of sophisticated modular systems where

each functional component enables the DNA complex to overcome a critical cellular barrier. Such true "artificial viruses" may then constitute a serious alternative to recombinant viruses for gene therapy applications.

Short Specialist Review

Adenovirus vectors

Monika Lusky
Transgene SA, Strasbourg, France

1. Adenovirus biology

For a better understanding of Ad vectors, the life cycle of adenovirus, extensively reviewed in Shenk (1996), is summarized below. The adenovirus is a nonenveloped, icosahedral virus of 60–90 nm in diameter. The genome of the most commonly used human adenovirus (group C, serotypes 2, 5) consists of a linear 36 kb double-stranded DNA molecule. The major viral capsid proteins consist of 240 hexon, 12 penton capsomeres, and 12 homotrimeric units of the fiber protein as the spike components of the penton capsomeres. The viral protein IX (pIX) forms 80 homotrimeric units and acts as cement protein for the viral capsid. A dominant pathway of cell entry is dictated by the interaction of the fiber protein's globular knob domain with the cellular coxsackie and adenovirus receptor (CAR). During the internalization process, a sequential disassembly of the virion occurs. The arrival of the viral DNA in the nucleus triggers the onset of early viral transcription.

Transcription of the viral genome occurs on both strands, and viral gene expression is coordinated through a precisely temporirally regulated splicing program of almost all the transcripts. Early transcription units (E1, E2, E3, E4) are differentiated from late ones (L), depending on the expression pattern relative to the onset of viral DNA synthesis (Figure 1). The first viral gene to be expressed is the major viral transcriptional transactivator encoded by the *E1A* gene, activating viral early transcription through the interaction with multiple transcription factors. As the E2 gene products (E2A: DNA binding protein, DBP; E2B: preterminal protein and DNA polymerase) accumulate, viral DNA replication can commence. The inverted terminal repeats (ITRs) of the viral chromosome serve as the replication origins. DNA synthesis occurs through protein priming mediated by the preterminal protein (pTP).

The adenoviral late genes, encoding mostly viral capsid proteins, begin to be expressed efficiently at the onset of viral DNA replication. The adenovirus late coding regions are organized into a single large transcription unit whose primary transcript is approximately 29 000 nt in length (Figure 1). This major late transcription unit (MLTU), controlled by the major late promoter (MLP), is processed by differential polyA site utilization and splicing to generate at least 18 distinct mRNAs, grouped into five distinct families, L1 to L5. With the accumulation of excess quantities of the viral capsid proteins, virus assembly begins with the formation of

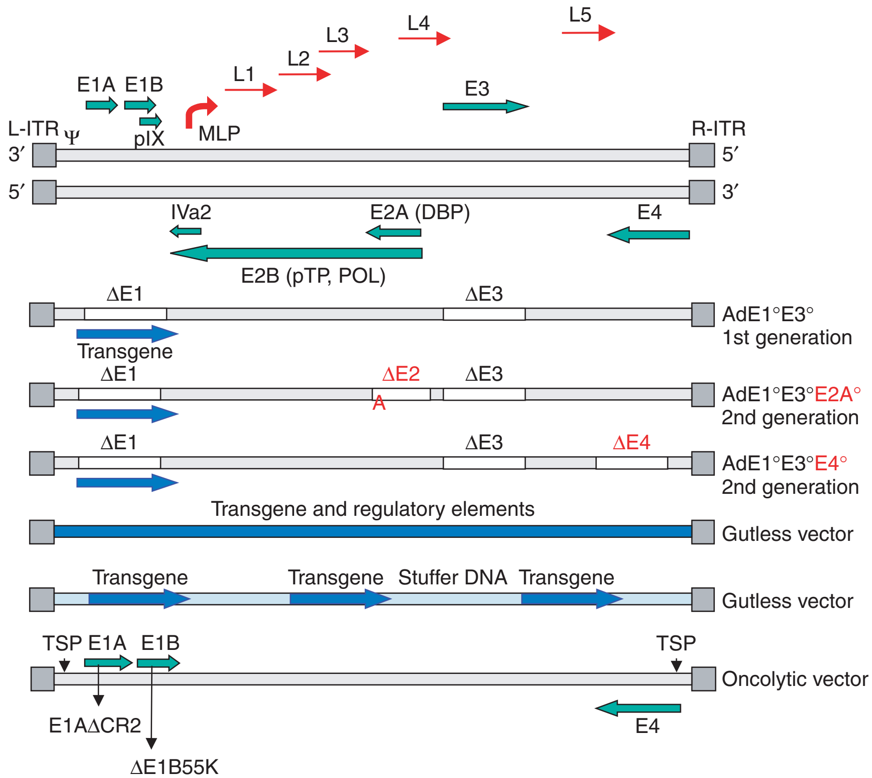

Figure 1 Schematic representation of the Ad5 genome organization and different species of recombinant Ad vectors. The direction of transcription of early (E) and late (L) mRNAs and of transgenes in the recombinant vectors is indicated by arrows. Deletions of viral regions and insertion of transgenes are depicted for first- and second-generation vectors as well as for gutless vectors. Typical genome modifications and the insertion of tumor-specific promoters (TSP) are indicated for an oncolytic vector

an empty capsid and, subsequently, a viral DNA molecule enters the capsid. The DNA-capsid recognition event is mediated by the packaging sequence (ψ), a cis-acting DNA sequence at about 260 nt from the left end of the viral chromosome. A single infectious cycle can lead to the production of 10^4 to 10^5 progeny particles.

2. Replication-defective Ad vectors

2.1. E1-deleted Ad vectors

Replication-deficient Ad vectors with critical viral functions deleted serve two purposes: (1) inhibition of viral spreading into the environment renders such viruses safe; (2) by deletion of viral genes, space is provided, which allows for the insertion of foreign transgenes. The earliest, first-generation recombinant Ad vectors have the E1 region deleted (E1). In addition, in most AdE1° vectors, the viral E3 region

is also deleted, as the E3 functions are not required for the viral life cycle in vitro (Shenk, 1996). In most cases, a heterologous expression cassette with a transgene is inserted in place of the E1 region (Figure 1). Such AdE1° and AdE1°E3° vectors can be propagated to high yields in permissive E1 complementation cell lines, such as 293 cells that provide the E1 functions in trans (Graham *et al*., 1977). 293 cells were generated by transformation of human embryonic kidney cells with sheared adenovirus DNA and carry the sequences between 1 and 4137 nt integrated into chromosomal DNA (Louis *et al*., 1997). Most AdE1° vectors carry an E1 deletion between approximately 400 and 3500 nt of the genome. Thus, an extensive sequence overlap exists between the E1 sequences present in the cell line and the sequences present in the vector. Owing to double crossover recombination events, the E1 sequences will be incorporated into the vector, leading to a replication competent adenovirus vector (RCA; Lochmüller *et al*., 1994). The strategy to prevent RCA was to eliminate any sequence overlap between vector sequences and viral sequences in the cell. This concept resulted in the generation of new E1 complementation cells carrying essentially only E1 coding sequences; these cells are either based on human embryonic retina cells (Per.C6; Fallaux *et al*., 1998) or human amniotic cells (Schiedner *et al*., 2000).

2.2. Ad vectors with multiple deletions

Disadvantages of AdE1° vectors including a high level of tissue toxicity and inflammation interfering with persistent transgene expression in many preclinical and clinical studies have stimulated further manipulation of the viral genome. Second-generation vectors with simultaneous deletions of several regulatory regions, AdE1°E3°E2A° or AdE1°E3°E4°, and the respective complementation cell lines (Lusky *et al*., 1998 and references therein) were generated (Figure 1). The additional deletions improve the cloning capacity to approximately 11 kb. Importantly, AdE1°E3°E4-modified vectors carrying the E4 ORF3 or E4ORF3 + ORF4 functions were able to allow persistent transgene expression in vivo, in selected animal models, in the absence of vector-induced toxicity and inflammation (Armentano *et al*., 1999; Christ *et al*., 2000). Multiple deleted Ad vectors might also be useful in cancer therapy (Senzer *et al*., 2004).

2.3. Gutless Ad vectors

Gutless, high-capacity Ad vectors lack all viral genes (gutless) and contain only the cis-acting sequences required for viral replication (ITRs) and the packaging signal (Schiedner *et al*., 2002). These vectors can accommodate up to 36 kb of nonviral DNA (high capacity), allowing the insertion of multiple expression cassettes, large genes, and their regulatory sequences (Figure 1). The toxicity and immunogenicity of these vectors in vivo is significantly reduced because of lack of viral gene expression, making long-term transgene expression possible. The production of a gutless Ad vector requires the presence of a helper virus, providing all missing viral functions in trans. In order to enrich for the gutless vector during production

and to reduce the contamination of helper virus in the purified gutless vector product, most systems are based on the genetic inactivation of the helper virus through recombinase-mediated excision of the packaging signal of the helper virus (Schiedner *et al*., 2002). This results in preparations of gutless vectors with a contamination of helper vector below 1%.

3. Replicative Ad vectors

Tumor-selective, replication-competent oncolytic viruses are attractive candidates as cancer therapeutics because they are intended to replicate and spread exclusively in tumor cells, leading to their destruction, while not affecting normal cells (Dobbelstein, 2004). Thus, the antitumor effect is not delivered with a transgene but by virus-mediated oncolysis and subsequent spreading of the virus in the tumor tissue. Two major approaches are pursued to achieve tumor selectivity of replication (Figure 1). One is to eliminate viral genes that are dispensable in tumor cells and the second is to replace viral promoters with tumor-specific promoters to express viral genes required for replication. The first approach exploits the fact that many tumors lack functional tumor suppressor genes such as p53 or the retinoblastoma tumor suppressor gene pRB (Johnson *et al*., 2002). Therefore, viral genes interacting with these host cell proteins should not be required for the replication of the virus in tumor cells. This concept has been explored with Ad vectors deficient in selected E1 genes. The prototype of such vector dl1520 (ONYX015) is deficient in p53 interaction due to a deletion in the E1B 55 kDa gene. This was the first therapeutic oncolytic virus shown to preferentially propagate in cancer cells based upon their p53 functional status (Bischoff *et al*., 1996).

Similarly, oncolytic Ad vectors with a mutation (CR2) in the pRB binding domain of the viral *E1A* gene have been designed toward selective replication in tumor cells with a disrupted retinoblastoma tumor suppressor protein (pRB) pathway. Since the pRB pathway is disrupted in nearly all human tumors, the oncolytic activity of a virus with the E1A-CR2 mutation should not be limited to tumors of a particular tissue type (Johnson *et al*., 2002). For such type of vectors, it was shown that its pRB selectivity could further be enhanced by replacement of the viral E1 and E4 promoter with the human E2F promoter (Johnson *et al*., 2002). The second approach for developing tumor cell selectivity has been the use of tumor-selective or tumor-specific promoters to control the expression of the adenoviral early genes E1, E2, or E4 and to restrict the oncolytic activity to the specific tumor targeted (Fernandez and Lemoine, 2004).

Both types of oncolytic vectors have been tested extensively in clinical trials, which have demonstrated a high level of safety of these vectors and very low toxicity levels. However, therapeutic efficacy of these oncolytic monotherapies has been limited so far (Kirn, 2002). Therefore, strategies are developed to increase the efficiency of oncolytic virus therapy. Genetic strategies include the incorporation of a therapeutic transgene into the oncolytic virus to generate an "armed therapeutic virus" (Hermiston and Kuhn, 2002). Several oncolytic vectors have been generated expressing prodrug-activating enzymes, and promising clinical results have emerged recently with an oncolytic Ad vector carrying a gene fusion

of the cytosine deaminase (CD) and the thymidine kinase (TK) gene (Hermiston and Kuhn, 2002).

4. Modification of Ad tropism

Owing to the broad tropism of adenovirus, significant efforts have been undertaken to de-target the virus from its natural tropism (CAR) and to retarget the virus to new receptors, with the goal of restricting transduction to the organ or tumor tissue of interest and to limit inflammatory responses. Another rationale for retargeting Ad vectors is that the CAR receptor, while expressed in most healthy tissues throughout the human body, is present in low levels in some target cell types and lack or downregulation of CAR has been reported for various tumor types (Anders *et al*., 2003). Owing to a detailed structure –function understanding of the fiber protein, residues in the fiber knob domain involved in CAR interaction as well as the HI-loop and the C-terminus in the knob for the suitable incorporation of ligands could be identified (Legrand *et al*., 2002). Viruses deficient in CAR interaction were de-targeted for the CAR entry pathway in vitro, but not in vivo, suggesting the existence of additional entry pathways in vivo. In this context, the ubiquitously expressed heparin sulfate proteoglycan molecules were described as an alternative Ad5 receptor (Dechecchi *et al*., 2001). Recent studies have shown that specific mutations in the fibershaft almost completely abolish the natural tropism of the virus in mice and nonhuman primates; however, the role of the fibershaft for the different entry pathways is not known (Smith *et al*., 2003). Several model ligands such as the integrin binding motif RGD or a heparansulfate proteoglycan binding polylysine peptide inserted into the fiber protein have been described to prove the concept of retargeting in vitro and have showed enhancement of tumor transduction in vivo (Wickham, 2002; Curiel, 2002). Fiber pseudotyping presents an alternative approach toward vector retargeting (Havenga *et al*., 2002). More recently, another capsid protein, pIX, was proposed as a candidate for the insertion of ligands. Incorporation of RGD or polylysine motifs at the extruding C-terminus of this protein showed enhanced transduction rates in vitro (Dimitriev *et al*., 2002; Velinga *et al*., 2004). Together, although it is now possible to generate fiber-modified viruses that show a specifically redirected binding and infection in vitro, the impact of these modifications is less clear in vivo.

An alternative or additional targeting strategy exploits the possibility of differential and tissue-/tumor-selective transcription through the use of tissue- or tumor-specific promoters (TSP). Thus transcriptional targeting aims to genetically limit the expression of the introduced gene or the replication of the virus to specific tissues or to the tumor mass through the use of promoter sequences whose activity is upregulated in the target tissues (Fernandez and Lemoine, 2004).

5. Toxicity and immunogenicity

Ad vector particles cause an acute immediate toxicity following systemic administration, resulting in a strong and rapid activation of chemokine expression by Ad-transduced macrophages. These initial events are followed by the cellular immune

response against vector-encoded MHC-presented proteins (St George, 2003). In addition, neutralizing antibodies raised against Ad vector particles in the host will prevent systemic readministration of the vector (O'Riordan, 2002). Approaches to overcome this problem include the sequential pseudotyping of Ad vectors (Havenga *et al*., 2004).

6. Ad vector construction

Initially, recombinant Ad vectors were generated in eukaryotic cells, such as in 293 cells, using ligation methods and homologous recombination (reviewed in Lusky *et al*., 2002).

Recently, several novel methods based on bacterial systems have been developed for the generation of Ad. Three basic methods have evolved to enable the manipulation of the full-length adenoviral genome as a stable plasmid and facilitate the efficient construction of precisely tailored and infectious Ad in *Escherichia coli*. Two powerful methods in use are based on homologous recombination (Chartier *et al*., 1996) and direct ligation (Mizuguchi and Kay, 1998) technologies. These methods combine major advantages over traditional approaches: (1) Manipulation of the viral genome at any point is possible. (2) Recombinant viral DNA is purified from individual bacterial clones and therefore generates homogenous virus preparations, obviating the need for tedious plaque screening and purification. (3) Importantly, and in contrast to the traditional in vivo approaches, these methods entirely separate viral vector construction from virus production. The first step is performed in bacteria and the second step takes place in the mammalian complementation cell line. The methods in use are simple, highly efficient, and can generate recombinant Ad vectors in a very short period of time (Lusky *et al*., 2002).

7. Conclusion and future direction

Cancer gene therapy is aiming at the destruction of malignant cells, whereas gene therapy for monogenetic disorders aims to restore a long-term function in target cells. Therefore, the requirements for viruses to be used for these applications are fundamentally different. In most clinical trials today, first- and second-generation Ad vectors are used in cancer gene therapy or in vaccination for tumor therapy or infectious diseases. For these applications, short-term and robust gene expression is often sufficient to show therapeutic effects. In contrast, gutless Ad vectors will find their applications in genetic diseases requiring long-term gene expression and potential readministration.

While much knowledge has been gained in the years of Ad vector development, many challenges remain. These include the development of strategies to (1) reduce vector-induced toxicity, (2) to enable readministration, (3) to specifically direct the vector to the targeted tissue in vivo specifically after systemic administration, and (4) to increase the therapeutic index of oncolytic vectors in vivo.

Short Specialist Review

Adeno-associated viral vectors: depend(o)ble stability

Richard O. Snyder
University of Florida, Gainesville, FL, USA

The adeno-associated viruses (AAV) are members of the family *Parvoviridae*, genus *Dependovirus,* and as the genus name implies, AAVs are dependent upon coinfection with a helper virus, such as an adenovirus, for efficient replication. The latent phase of the life cycle of these nonpathogenic viruses has made them attractive for development as gene transfer vectors (Muzyczka, 1992). As AAV vector technology has improved, the safety and efficacy of AAV-mediated gene transfer in animal models has been demonstrated (reviewed in Snyder, 1999), and the vectors have been shown to persist and are safe in humans (Wagner *et al*., 1999; Flotte *et al*., 2003; Stedman *et al*., 2000; Manno *et al*., 2003; Janson *et al*., 2002; During *et al*., 2001; Flotte *et al*., 2004).

To date, more than 100 serotypes of AAV have been identified (Gao *et al*., 2004). Of the vectors that have been characterized, some are capable of infecting different types of cells from several species, and the cellular receptors that determine tropism are being investigated. For AAV2, three cellular receptors have been identified: heparin sulfate proteoglycan, the fibroblast growth factor receptor (FGFR1), and $\alpha V\beta 5$ integrin. Serotypes other than AAV2 interact with different cell surface molecules (Di Pasquale *et al*., 2003). The difference in transduction efficiency of these vector serotypes in different tissue targets can be quite significant, and matching vector serotype to organ targets is an area of intense investigation.

AAV virions contain a single-stranded DNA genome of 4.7 kb and both plus and minus strands are packaged equally. Infectious clones have facilitated the study of the genetics of the virus, defining two major open reading frames (ORFs). The *cap* ORF encodes the viral capsid proteins VP-1, VP-2, and VP-3 that assemble into particles with $T = 1$ icosahedral symmetry (Xie *et al*., 2002). The *rep* ORF encodes the four nonstructural Rep proteins that have been shown to possess functions required to replicate the genome, modulate transcription from AAV and heterologous promoters, mediate site-specific integration into the human genome, and encapsidate single-stranded genomes. The palindromic terminal repeats are 145 nucleotides that form T-shaped structures and encode sequences required for packaging, integration, and rescue, and also serve as the origins of DNA replication.

In tissue culture cells, there are preferred sites within the human genome where wild-type AAV2 establishes a latent infection that can be stable for years and many passages. The highly preferred site located on chromosome 19q13.3-qter (called

AAVS1) was initially characterized by Kotin *et al*. (1992), and subsequent analyses have shown that as little as 33 bp of AAVS1 is required to direct integration. DNA binding experiments demonstrated the ability of the Rep 78 and 68 proteins to bind to AAVS1 and mediate the juxtaposition with the AAV2 ITR. A search of the May 2004 freeze of the human genome using the UC Santa Cruz genome browser (**http://genome.ucsc.edu**) did not reveal the presence of any significant regions of AAV DNA homology (M. Nickerson and R. Snyder, unpublished observation). Gao *et al*. (2004) were able to isolate AAV genomes from a variety of human tissues. This raises two possibilities: (1) that AAV genomic sequences may not be integrated in the human genome but episomal forms were coisolated during the total DNA isolation procedure used by Gao *et al*. or (2) the compilation of the consensus human genome sequence may exclude differences between sequenced DNA samples such that unique sequences, including integrated AAV, may have been "filtered out".

The long-term and stable gene expression in normal, mature, and quiescent tissue has been achieved in a variety of animal models and organ targets using rAAV vectors encoding therapeutic and marker proteins (*see* Article 92, **Hematopoietic stem cell gene therapy**, Volume 2, Article 93, **Gene therapy in the central nervous system**, Volume 2, Article 94, **Cardiovascular gene therapy**, Volume 2, Article 101, **Gene transfer to skeletal muscle**, Volume 2, Article 102, **Gene transfer to the liver**, Volume 2, and Article 103, **Gene transfer to the skin**, Volume 2). These studies demonstrate the versatility of rAAV vectors and their applicability to treating a broad spectrum of human diseases. Following rAAV transduction, vector dose-dependent and sustained protein expression has been achieved utilizing constitutive promoters from cellular and viral sources, and exogenously regulated promoters based on the tetracycline (Rendahl *et al*., 1998) or rapamycin (Rivera *et al*., 2004) systems (*see* Article 104, **Control of transgene expression in mammalian cells**, Volume 2). Acute toxicity has not been observed by histological and serum biochemical analyses following transduction of a variety of tissues. Safety studies to support clinical trials require sensitive, reproducible, and validated assays carried out under Good Laboratory Practices (GLP) regulations.

Long-term studies in animals and humans indicate that few serious adverse events (such as tumorigenesis and germline transmission) arise following rAAV-mediated gene delivery (Manno *et al*., 2003; Wagner *et al*., 1999; Tenenbaum *et al*., 2003). In a study carried out by Donsante *et al*. (2001), data after 1 year in a small number of MPS-VII mice showed that liver tumors developed following IV neonatal transduction. This result seems to be an exception because similar long-term liver transduction of normal animals using AAV vectors have been carried out at higher input doses, and these have not resulted in liver tumors (Snyder *et al*., 1997; Mount *et al*., 2002). Integration of rAAV viral vectors (lacking the *rep* gene) into the genome of human tissue culture cells appears random. In animal models, sites homologous to AAVS1 are not found and studies to determine the status of the rAAV vector following in vivo transduction indicate that the vector genome may integrate inefficiently at random sites in head-to-tail concatameric arrays with a preference for transcribed genes (Nakai *et al*., 2003). Conversely, AAV has been detected in episomal form in lung tissue, skeletal muscle, and liver, and an episomal

intermediate may exist before integration. Targeted integration of wild-type AAV has been demonstrated in vivo in transgenic rats and mice harboring AAVS1.

Humoral immunity to multiple AAV serotypes preexists in 80–90% of humans; of this population, approximately 20–50% carry neutralizing antibodies to the capsid. Administration of AAV vectors to animals elicits a humoral response to the AAV capsid proteins, except when the primary transduction event is accompanied by immunosuppressive therapy. The repertoire of vectors derived from different AAV serotypes could allow repeat dosing or primary dosing in patients with preexisting antibodies (*see* Article 99, **Immunity and tolerance induction in gene therapy**, Volume 2).

Sustained expression of certain foreign proteins in immunocompetent animals has been achieved using rAAV vectors. Transient infiltrates following transduction of murine skeletal muscle have been observed between 2 and 6 weeks, but transduced cells were not eliminated. It was shown that rAAV vectors transduce dendritic cells very poorly, and thus induction of an immune response to transgene products may not be sufficiently primed (Wang *et al*., 2004), but this can be route and dose dependent. Additionally, the slow rise in gene expression may help in the development of tolerance toward a foreign gene product. Steady state protein expression has a characteristic 2–4-week delay following transduction in vivo that can be explained in part by the need to create a transcriptionally active template that is concatamerized and/or integrated into the cellular genome. The conversion of the viral single-stranded genome to a double-stranded molecule that is a template for RNA polymerase is a rate-limiting step for AAV transduction.

During the lytic cycle, greater than 10^6 genomes, 10^7 preformed capsids, 10^6 total virions, and 10^4 infectious virions are generated per cell. The adenoviral (Ad) gene products that play a role in the AAV lytic cycle include E1A, E1B, E2A, E4, and VA, and these act throughout the AAV replicative cycle to promote AAV production. The herpesviruses can also supply helper functions but the *HSV* genes responsible for helping AAV have distinct functions from the Ad genes and include a subset of genes required for HSV DNA replication.

For vectors, the AAV inverted terminal repeats (ITRs) supply the cis-acting sequences for production and transduction (Samulski *et al*., 1989), although sequences located inside of the ITRs possess some of these activities (Nony *et al*., 2003). A transgene can replace the AAV coding sequences because both the *rep* and *cap* gene products can be supplied in trans to make infectious rAAV virions (Samulski *et al*., 1989). The primary disadvantage in the use of rAAV vectors is the size limitation of approximately 5000 nucleotides for a recombinant genome that is capable of being packaged.

In standard methods used to produce rAAV vectors, helper and vector plasmids are cotransfected into tissue culture cells along with the Ad genes required for AAV vector production, and no infectious adenovirus is generated by this method. Approximately 100–200 infectious particles (5×10^3–5×10^4 packaged vector genomes (vg)) are produced per cell and suitable quantities of vector can be produced for early human clinical trials using this technology. For increased scale, advances such as the creation of stable packaging cell lines or helperviruses harboring the AAV genes have been developed. AAV vector sequences have been incorporated into the E1A region of Ad, and in the presence of *rep* and *cap* (e.g.,

supplied in a stable cell line), rAAV vectors can be produced at titers similar to traditional means (~100–200 infectious units per cell). Incorporating the AAV genes into Ad has been very difficult and is likely due to Rep toxicity toward adenovirus that may be of similar origin to the toxicity seen in tissue culture cells. Herpesviruses harboring the AAV genes have been constructed for AAV production and can achieve outputs of 5000 infectious units per cell (nearly equal to wild-type yields). Production of rAAV using cultured insect cells and three recombinant baculoviruses encoding AAV2 Rep proteins, capsid proteins, and a recombinant AAV vector cassette has been described recently with yields approaching 5×10^4 vg per Sf9 cell.

The size and physiochemical stability of parvoviral virions allows harvest and purification by traditional methods utilized in the industrial manufacture of protein therapeutics. The virions are very small (18–26 nm) and stable to a wide range of temperatures (−80°C to 56°C), pH 3–9, sonication, microfluidization, solvents ($CHCl_3$), detergents, proteases, and nucleases. The virions are also stable during precipitation using $(NH_4)_2SO_4$, PEG, or $CaCl_2$, and during column chromatographic procedures. Purifying rAAV vectors using automated column chromatography is economical, scalable, and reproducible, and can be validated in compliance with current Good Manufacturing Practice (cGMP) regulations. In addition, the stability of the virions is suitable for long-term storage, and direct in vivo administration.

Characterization of the vector stocks utilizing robust, rugged, and reproducible testing methods needs to be performed to develop and monitor the clinical manufacturing process, evaluate product, and compare animal studies using different vector lots (Table 1). The level of protein contaminants and the proper ratio of the AAV capsid proteins can be assessed on stained denaturing protein gels, and by immunoblotting using antibodies to possible contaminants (such as adenovirus proteins and bovine serum albumin) and AAV capsid proteins. Total and infectious particle titers need to be accurately determined to evaluate dosing and the total particle:infectious particle ratio. Ideally, the titering incorporates the use of an accepted reference standard, so doses that are prepared by different laboratories can be compared. In addition to vector characterization, product safety testing ensures patient protection. Levels of infectious adventitious viruses can be evaluated using plaque assays or cytopathic effect (CPE) assays. Contaminating cellular and plasmid DNA can be assessed by PCR or hybridization. The degree of replication competent

Table 1 AAV clinical batch testing

Safety	Characterization
Sterility including bacteriostasis/fungistasis	Purity: Silver staining/Coomassie blue
Mycoplasma	Potency: Infectious unit titer
Endotoxin	Strength: vector genome titer
In vitro adventitious viral contaminants	Strength: particle titer
General safety	Identity
rcAAV	Appearance
Residual host cell DNA	

AAV (rcAAV) generated through homologous or nonhomologous mechanisms can be determined using replication center assays, PCR, or Southern blot analyses.

Several parallel efforts are advancing the use of rAAV vectors for treating human diseases. For several serotypes, large-scale manufacturing technology is being developed that will generate vector batches that are safe, pure, potent, and stable. The collection of AAV serotypes is being matched to specific organs and cell types to maximize uptake efficiency, and these vectors will be tested in the clinic soon. Improvements in vector expression cassettes have achieved tissue specificity and regulation, and increased vector potency that provides therapeutic benefit at lower vector doses and less cost. Well-designed acute and long-term toxicology studies are being conducted to better understand the safety profile in animals, and experience in humans is accumulating. Finally, with the sequencing of the human genome, matching therapeutic genes to specific diseases has the potential for different molecular approaches for treating each disease.

Notice

RS is an inventor on patents related to recombinant AAV technology and owns equity in a gene therapy company that is commercializing AAV for gene therapy applications. To the extent that the work in this manuscript increases the value of these commercial holdings, RS has a conflict of interest.

Short Specialist Review

Retro/lentiviral vectors

Douglas E. Brown and Andrew M. L. Lever
University of Cambridge, Cambridge, UK

Until the discovery of retroviruses and the elucidation of their life cycle, it was believed that DNA was the primary genetic store for most organisms and that this was transcribed into RNA, but that the reverse could not occur. Some viruses used RNA only, copying their RNA genome into mRNAs and new genomes. The identification of a family of viruses in which the virus particle contained an RNA genome, which acted as a template for a DNA copy that integrates into the DNA of the infected cell, altered this dogma. Identification of the enzyme responsible, reverse transcriptase, gave the viruses their name and earned the Nobel prize for Temin and Baltimore. Very soon it was realized that if one could subvert this system it could be used to deliver and integrate heterologous genes into the DNA of a cell for research and even therapeutic purposes.

Research on the known animal (mainly mouse) and avian retroviruses would have undoubtedly continued at a vigorous pace, but the emergence of a pathogenic human retrovirus HIV, which turned out to be a member of the relatively obscure lentivirus group of retroviruses, revolutionized the field. Unprecedented amounts of money and research effort were invested in understanding this virus, and it is now probably the most intensively studied genetic sequence ever. Lentiviruses are retroviruses but with a more complex array of regulatory genes and with the critical difference of being able to enter into and integrate into cells that are not undergoing mitosis. Thus, for gene delivery to cells of the nervous system (*see* Article 93, **Gene therapy in the central nervous system**, Volume 2), muscle (*see* Article 101, **Gene transfer to skeletal muscle**, Volume 2), and liver (*see* Article 102, **Gene transfer to the liver**, Volume 2), the lentivirus subfamily has opened up a new vista of possibilities over and above those available using earlier "simple" murine and avian viruses (Lever, 2003; Quinonez and Sutton, 2002; Trono, 2001).

A simplified retroviral life cycle is shown in Figure 1. To generate new retroviral vectors, it is necessary to understand the process from the time point at which the viral RNA in the cell is first transcribed through to the budding of the new viruses (5–10). The period (1–5) from binding of the virus to its target cell through to the transcriptionally active integrated DNA provirus must be understood to use the vectors to infect or "transduce" cells efficiently (Delenda, 2004).

To generate vectors, it was necessary to find out how the virus captures its own RNA from amongst the many species present in the living cell. Regions of the genomic RNA were identified, which, when deleted, did not affect protein

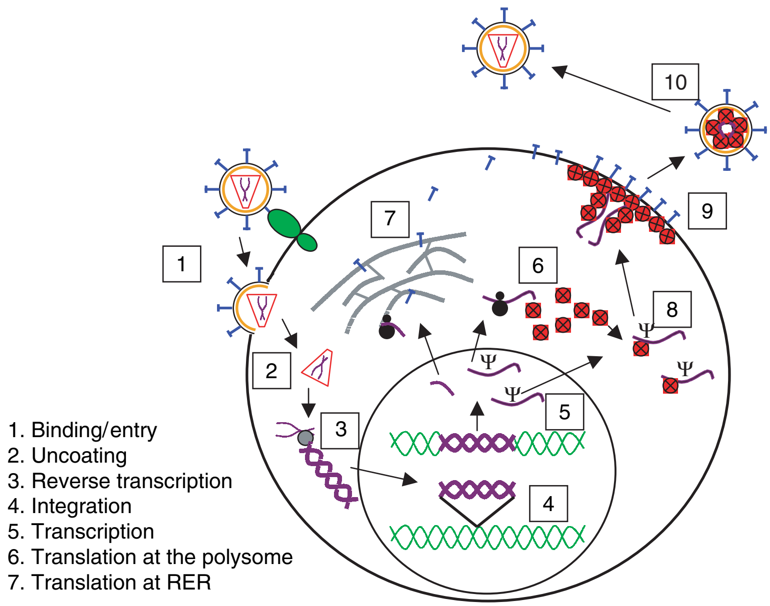

Figure 1 Simplified retroviral life cycle

coding but led to the production of virus particles devoid of genomes. Thus, "packaging signals" (Ψ) were discovered. Eliminating these from a construct encoding the viral proteins generated "empty" virus particles (Jewell and Mansky, 2000). Incorporating this same Ψ region into a heterologous RNA and expressing it in the same cell as the virus proteins led to the new chimeric RNA being captured, packaged, and incorporated into the budding virus (Lever, 2000; Linial and Miller, 1990). If the viral/vector particle infects a cell, this RNA is reverse-transcribed and integrated into that cell using the enzymes carried in the virus.

Retroviruses have another unique property amongst viruses, that of encapsidating a pair of RNA genomes – they are diploid (Haddrick *et al*., 1996). This is thought to be advantageous in repairing the reverse transcript if one copy is defective, and it also contributes to genomic diversity since two slightly different RNAs from different proviruses can, in theory, be packaged in the same particle and, by template hopping during reverse transcription, recombination can occur.

For vectors, this poses a potential danger since even if a packaging signal is deleted, the leakiness of the system means that there may still be a risk of encapsidating a small number of the mRNA molecules that code for the viral proteins along with the gene delivery vector containing the packaging signal. Recombination could recreate a full-size infectious virus. This is very undesirable for murine virus systems since the high risk of insertional mutagenesis when a replication competent vector is produced is well established (Kohn *et al*., 2003). Recombination to recreate an intact HIV would also clearly be disastrous. Eliminating this risk has been the focus of much effort, and considerable progress has also been made. First, the virus protein-coding construct is separated out into cassettes encoding either the structural (Gag) and enzymatic (Pol) proteins or the

envelope (Env) gene-coding region. In lentiviruses, the regulatory protein Rev is sometimes also required and is provided on a third construct (Gasmi *et al*., 1999). These two or three DNAs are then introduced into cells together with the gene vector with its intact packaging signal. Transient transfection or stable expression of the constructs have both been attempted for coexpression of these genes. For simple viruses, stable expression of some or all of these constructs in packaging or producer cell lines has been readily achieved (Cosset *et al*., 1995). Lentiviruses, probably because of cellular incompatibilities, have proven to be difficult to express stably although newer inducible cell lines have been developed (Farson *et al*., 2001; Kuate *et al*., 2002; Sparacio *et al*., 2001). In lentiviruses, building on many years of receptor research, the viral envelope is commonly substituted by a heterologous envelope, commonly from the Rhabdovirus, Vesicular Stomatitis Virus (VSV). The G-protein for VSV coats (pseudotypes) the particles well, makes them more stable, more easily purified and concentrated, and confers considerably wider tropism (Burns *et al*., 1993).

For all retroviral vectors, efforts have been made to eliminate the risk of recombinational reconstruction of a native virus. This has involved careful removal of all nonessential sequence from all the constructs to minimize regions of homology (Zufferey *et al*., 1997; Dull *et al*., 1998). Codon optimization reduces sequence homologies and has been shown to enhance expression (Fuller and Anson, 2001). In lentiviruses, the Rev/Rev responsive element (RRE) nuclear export system has been supplemented by export sequences from other viruses including the Mason–Pfizer Monkey virus constitutive transport element (CTE) (Srinivasakumar and Schuening, 1999) and the Woodchuck hepatitis posttranscriptional response element (WPTRE) (Zufferey *et al*., 1999). All of these enhance export of the transgene (*see* Article 104, **Control of transgene expression in mammalian cells**, Volume 2) in the target cell, but in the producer cell, despite equivalent nuclear export of RNA, the Rev protein, in concert with its response element appears to have extra effects on enhancing vector titer, suggesting it has additional roles in virus assembly and RNA encapsidation (Anson and Fuller, 2003). Vectors now commonly contain both the Rev/RRE system and a second nuclear export signal.

Compared to some viral vectors like those based on Adenovirus (*see* Article 96, **Adenovirus vectors**, Volume 2), retro/lentiviral vectors are of lower titer. 10^7 infectious units per milliliter is readily achievable and using concentration procedures, this can be raised further. Of the cells that are transduced by vectors, the proportion in which the transgene is transcriptionally active is uncertain. Simple retroviruses have LTR regions, which may be subject to transcriptional silencing, as are some heterologous promoters when used in vivo long term (Pannell and Ellis, 2001). Lentivirus vectors, if transcriptionally active on transfer, appear to maintain gene expression. More work is needed on this aspect of their use.

Murine retroviral vectors are one of the most widely used vectors in the clinic (*see* Article 100, **Gene transfer vectors as medicinal products: risks and benefits**, Volume 2). The clear definition of their packaging signals and the strictness of RNA encapsidation (Linial and Miller, 1990; Linial *et al*., 1978) together with the ease of production of packaging cell lines (Miller, 1990) has been influential in their popularity. Perhaps the most stunning success has been the transfer of the γ-C receptor gene to blood stem cells of children with severe combined

immunodeficiency (Cavazzana-Calvo *et al*., 2000). Although two children have suffered a vector insertion–related lymphoproliferative disorder (Hacein-Bey-Abina *et al*., 2003a,b), both have now been successfully treated and are in remission, bringing the number of successfully treated and clinically well children given this gene therapy to over 15. Some of these would undoubtedly be ill or dead by now and the long-term outlook for them all in the absence of this treatment was very poor. Despite the logistic barriers to producing clinically useful quantities of vector and the use of transient transfection processes in manufacture, the first lentiviral vector based on HIV-1 is now in clinical trial (Dropulic, 2001). It can only be a matter of time before this pioneering study is joined by others using the specific advantages of lentiviruses.

Retroviral vectors have a niche for long-term integrated gene expression. Their requirement for cell division can be used to advantage to transduce toxic genes into tumor cells in the background of nondividing normal cells such as in treatment of tumors in the central nervous system. They are useful for targeted treatment and ex vivo delivery to selected cell populations. Lentiviruses also have a growing potential. They seem to maintain gene expression, possibly linked to their propensity to integrate into active chromatin, while long-term gene delivery to and expression in mitotically inactive cells is a real advantage (Naldini *et al*., 1996). Their close rival, Adeno associated viruses (AAV) (*see* Article 97, **Adeno-associated viral vectors: depend(o)ble stability**, Volume 2) have the drawback of a much smaller gene-carrying capacity. Lentiviral vectors do not, however, penetrate very well into tissue and require a relatively long exposure to the target tissue for effective transduction. This may be solved by some of the newer polymer delivery systems (Dishart *et al*., 2003). The use of a heterologous envelope obviates the risk of recombinational formation of HIV; however, the later risk of gene mobilization by an exogenous HIV infection needs to be borne in mind. Insertional mutagenesis remains a specter but as long as they are being used for severe illnesses for which there is no alternative better treatment and for which the prognosis is very poor, this is a risk worth running. New strategies strengthening polyadenylation signals, using insulator sequences or locus control regions and tissue-specific promoters will reduce the risk of read-through activation of adjacent genes (*see* Article 104, **Control of transgene expression in mammalian cells**, Volume 2).

In the long term, all of these vectors will provide the building blocks for synthetic vectors, which incorporate useful individual proteins and cis-acting sequences, to create truly nonviral vectors that are safe and efficient. As yet, however, the efficiency with which viruses enter cells and deliver their genetic material dwarfs anything we have managed with synthetic vectors – but they have had many more years of practice.

Short Specialist Review

Immunity and tolerance induction in gene therapy

Jean Davoust, Nicolas Bertho, Carole Masurier and David Gross
Généthon, Evry, France

1. Introduction

The goal of gene therapist facing the three-headed Cerberus guardian of the immune system composed of innate, cellular, and humoral effectors is to understand and control immune responses induced after gene transfer in order to design safe and efficient gene therapy protocols (Second Cabo gene therapy working group, 2002). This is of central importance in order to enable survival, growth or persistence of the corrected cells, which express a foreign antigen absent during the initial development of the immune system. As dendritic cells (DCs) maintain and/or initiate peripheral tolerance against self antigens and can eventually be tailored to induce tolerance against foreign antigens expressed after gene transfer, they are central to this question and careful attention should be devoted to DC/gene therapy vector interactions both in animal models and in humans in vitro cells.

Immune responses can either be immediate in case of hypersensitivity reactions to the vector, or adaptive and linked to the development of humoral and cellular responses to vectors and transgene products. Preexisting immunity to viral vectors can notoriously obviate gene engraftment, and the fine dissection of such responses must be pursued to identify the effector arms leading to rejection of transduced cells (Kafri *et al*., 1998; Brown and Lillicrap, 2002; Wang *et al*., 2005). Preexisting responses against the vector may not only hamper gene delivery, but may behave as an adjuvant eliciting adaptive responses to the transgene itself. This risk can, in principle, be evaluated in animal model, when the transgene product bears nonself–amino acid sequences. This is usually not straightforward, as one needs to design appropriate animal models with precise mutations in the target gene, and to deliver animal-matched gene sequences to correct the disease.

Several approaches can be used to counteract the deleterious effects of immune responses on transduced cells, in order to maintain long-lasting corrections in treated tissues. Nonspecific immunosuppressive treatments improve the duration of the gene transfer (Jooss *et al*., 1996; Jooss *et al*., 1998) but may compromise the vital functions of the immune system of the host. Antigen delivery to privileged tissues such as liver can induce a state of tolerance (Dobrzynski *et al*., 2004;

Mingozzi *et al*., 2003), and a general antigen-specific cotreatment has recently been proposed on the basis of adoptive transfer of antigen-educated regulatory CD4+ CD25+ T lymphocytes to inhibit the responses against recombinant adenovirus-associated vector (rAAV) transgene expression in the host (Jooss *et al*., 2001).

Several factors influencing the presentation of non-self antigens expressed from recombinant vectors should be taken into account, including the nature of the vector itself and the ability of the transgene to transduce directly the dendritic cells or to be cross-presented by DCs after the capture of transduced cell bodies (Sarukhan *et al*., 2001a,b; Berard *et al*., 2000; Guermonprez *et al*., 2003). DCs are the first line of immune cells encountering vector preparations and transgene products in vivo, and as such represent an important research field to be explored to evaluate the orientation of immune responses in each therapeutic setting (Pulendran, 2004). DCs also represent highly valuable tools to identify the epitopes being processed and presented by MHC class I and MHC class II molecules after antigen capture in the form of either viral particles or cell fragments containing transgene products (Guermonprez *et al*., 2002).

2. Deciphering dendritic cells/viral vector interactions

DCs play an important role in the distinction of self/non-self antigens, both in the thymus where they present self antigen to developing T lymphocytes and delete autoreactive T cells, and in the periphery where they are thought to activate immunoregulatory T cells. Although of major importance, central tolerance mechanisms are ineffective for a variety of self antigens either uniquely present in the periphery, expressed at late stages of the formation of the T cell repertoire, or for Ag that engage promiscuous T cell receptors that cross-react with self determinants. As recently proposed, DCs that reside in the periphery may migrate to secondary lymphoid organs at the steady state, inducing tolerance through cognate interactions with regulatory T cells (Steinman and Nussenzweig, 2002; Steinman *et al*., 2003). Conversely, DCs that have captured antigens in the periphery and/or are activated by a series of inflammatory cytokines, adjuvant components, and cell–cell contacts, may initiate immunostimulatory responses in lymph nodes leading to the expansion of B and T cell effectors.

The underlying role of DCs, and probably of other cell types expressing class II MHC molecules, emerges therefore as an important element in the initiation of immune responses to the vector and/or transgene products and in the induction of peripheral tolerance to specific antigens. Previous anatomo-pathology studies carried out in human lymph node draining inflammatory lesions have allowed to determine that immature DCs of the Langerhans type (LC) can be found in enflamed lymph nodes and that partially matured LCs acquired migration responsiveness to lymph nodes chemokines in vitro. These observations indicated that LCs as well as other DC subtypes can transport antigens to secondary lymphoid organs to induce either immunity or peripheral tolerance depending on their maturation stages. This transport and the local production of IL-10 could play a central role in the tolerization process of CD4+ T cells, and consequently of CD8+ T cells recruited in the lymph node microenvironment because of specific recognition

of transgene epitopes. Two lines of research need, therefore, to be conducted to tackle subtle interactions of DCs and gene therapy vectors, namely, the in vivo evaluation of DC activation by currently used gene transfer protocols, and the in vitro evaluation of human DC interactions with gene therapy vectors to qualify vector preparations for immune innocuousness and assess the tropism of transgene promoters.

2.1. Interactions between gene therapy vectors and antigens presenting cells

With the promising use of various vectors of clinical interest, such as AAV (adeno-associated virus vectors) and LV (lentivirus vectors), it is now important to assess the transduction efficacy according to the promoter selected for each application, and the ensuing activation of human DCs (activation of endocytosis, migration, and maturation properties). This knowledge will be helpful to minimize the immunogenicity of viral vectors preparations. For this purpose, one can differentiate different subtypes of DC (interstitial type, Langerhans, or plasmacytoid DCs) derived either from circulating monocytes or from CD34+ progenitors, to explore their transduction efficacy with nonreplicative viral vectors, their antigen presentation capacity after transduction, and the ensuing initiation of T cell responses.

2.2. Prospects for in vivo manipulation of dendritic cells and tolerance induction to gene therapy

In the long run, gene therapists wish to understand how DCs initiate peripheral tolerance against self antigens and can be tailored to induce tolerance against foreign antigens, which are expressed in cells corrected by gene therapy. DCs are cornerstones of immunity being effective antigen-presenting cells that play prominent roles in infectious diseases, immune disorders, tolerance, and vaccination (Banchereau and Steinman, 1998; Banchereau *et al*., 2000). At present, it is commonly believed that in the steady state, nonactivated DCs induce tolerance to peripheral self antigens by presenting these antigens but failing to engage T cell costimulation (Dhodapkar and Steinman, 2002). However, upon signal reception from pathogens, inflammatory or immune mediators, maturing DCs present antigens to costimulation-dependent, naive T cells and initiate immune responses. The mechanisms of T cell tolerance include anergy, changes in T cell development, induction of regulatory T cells, and T cell deletion. It is commonly accepted that targeting the foreign antigens to DC subpopulations in an immature state, or preventing DC maturation by direct interference on activation factors, will lead to the establishment of antigen-specific immune regulation.

DC-based tolerance induction implies, therefore, that one could target immature DCs and activate regulatory T cells in the steady state, to exert a suppressive role on specific CD4+ and CD8t T lymphocytes. The cell-to-cell contact dependence and the antigen specificity of the induction of regulatory T cells are now actively

explored (Tang *et al*., 2004; Tarbell *et al*., 2004) and can be summarized by a three-step model (Steinbrink *et al*., 2002; Mahnke *et al*., 2002; Jonuleit *et al*., 2002; Jonuleit *et al*., 2001) in humans: (1) APCs, probably resting DCs, activate CD4+ T regulatory cells, (2) they also interact with conventional CD4+ T cells resulting in the development of additional suppressor T cell populations, (3) these induced CD4+ T regulatory cells suppress the proliferation of freshly isolated conventional CD4+T cells via a process partially mediated by soluble TGF-ß, and suppress also CD8+ T cells (Dhodapkar and Steinman, 2002; Piccirillo and Shevach, 2001). Immature DCs can, in addition, induce regulatory CD8+ T cells (Dhodapkar and Steinman, 2002), and activated CD4+ CD25-regulatory T cells secrete huge amounts of IL-10, which spread the response and maintain DCs and monocytes in an immature or inactive stage in inflammatory sites. This model focuses our attention on MHC class II antigen presentation as a key element in inducing antigen-specific CD4+ T cell help and Ag-specific CD4+ tolerance. One may conceive that from an initial decisive interaction with DCs, which presumably occurs in draining lymph nodes, the CD4 T cell compartment generates either T helper or T regulatory responses, which determine the fate of B cells and cytotoxic CD8+ T cells effectors.

In future prospects, it seems therefore crucial to delineate epitopes presented by MHC class II molecules using transgenic strains for HLA-DR MHC class II molecules, gearing regulatory T cell responses.

3. Immunological design of transgene-specific tolerance with CD4+ CD25+ regulatory T cells

Successful gene transfer requires immunosuppression to arrest the immune response and achieve expression of the engrafted gene. However, long-lasting and life-threatening immunosuppression is undesirable in most therapeutic applications. Alternative antigen-specific immunosuppressive protocols can now be designed with regulatory T cells. The role of CD4+ CD25+ regulatory T cells (Tregs) and of IL-10 producing T cells during the control of immune responses has now been established in several situations: (1) transplantation (Waldmann and Cobbold, 2004; Walsh *et al*., 2004), after which the graft versus host disease may be alleviated by the donor's CD4+ CD25+ regulatory T lymphocytes (Taylor *et al*., 2004; Trenado *et al*., 2003); (2) autoimmune pathologies and chronic inflammations, where regulatory T lymphocytes can attenuate the immune responses; (3) tolerance induction by persisting pathogens, and tolerance induction in the airway and intestinal tracks (Shevach, 2002; Sakaguchi, 2004; O'Garra and Vieira, 2004). Although their mode of action is still a matter of debate, the CD4+ regulatory T cell subsets can probably interact with antigen-presenting cells (APC) loaded with fragments from foreign proteins to exert their suppressive role. The recruitment of antigen-specific regulatory T cells at the site of gene transfer and/or in draining lymphoid organs should be a mean to nullify the initiation of immune responses by APCs carrying transgene products.

The potency of antigen-specific Tregs to counteract immune responses after gene transfer can be evaluated using regulatory T lymphocytes bearing a transgenic T

cell receptor that recognizes a single epitope derived from a model transgene, such as the hemagglutinin (HA) protein of Influenza virus. Indeed, HA-restricted Tregs transferred into unconditioned animals could exert their suppressive function on both humoral and cellular immune responses and blocked the rejection of muscle fibers transduced with the HA model transgene (Gross *et al*., 2003). To gain insight in the suppressive mechanism, it is now of importance to explore the type of DCs involved as well as the robustness of the phenomenon of immune tolerance. As discussed above, it is likely that in this system, DCs either capture foreign Ag and present them through a cross-presentation pathway (Guermonprez *et al*., 2003) or express the transgene directly to prime regulatory T cells.

4. Monitoring immune responses through identification of epitopes present on transgenes

As cellular immune responses may compromise long-term expression in various gene therapy strategies, studying the cytotoxic responses generated after gene transfer in diseased animal models remains of central importance. To explore humanized HLA-restricted responses in a preclinical setting, it is therefore desirable to construct models in which the mutated phenotype is present in mice carrying human HLA class I molecules such as the most represented HLA-A*0201 in Caucasian populations (Firat *et al*., 1999). Choosing as a model mdx mice lacking full dystrophin sequence expression due to a stop codon on exon 23, the HLA-A*0201 character would be able to educate a "humanized" T cell repertoire, which contains reactivities to nonself dystrophin sequences, allowing therefore the identification of HLA-A*0201 dystrophin rejection epitopes. In such mice, cellular immune responses may block long-term restoration of wild-type dystrophin provided by gene therapy treatments, and cytotoxic T cell reactivities are to be analyzed by combining epitope prediction with in vivo cytotoxic assays after gene delivery using full-length dystrophin plasmid. These studies led to the identification of a human specific HLA-A*0201 epitope hDys1281 (Ginhoux *et al*., 2003) and may lead to the identification of new epitopes revealed only on the mdx/HLA-A*0201 background.

Recent results indicated that in contrast to plasmid delivery, rescue of muscle dystrophin expression by exon-skipping after administration of either an oligonucleotide (Lu *et al*., 2003), or an AAV vector expressing antisense sequences linked to a modified U7 small nuclear RNA (Goyenvalle *et al*., 2004) restored long-term expression of dystrophin within muscle fibers. Both of these restorations failed to trigger immune rejection of muscle fibers expressing the corrected dystrophin sequence. The above-mentioned mdx/HLA-A*0201 animals may, therefore, represent appealing models to compare the induction of CTL activity against dystrophin depending on the gene repair protocol being used. Preliminary results indicated that the dystrophin exon skipping procedure, which restores nearly full-length dystrophin messenger mRNA (Lu *et al*., 2003; Goyenvalle *et al*., 2004), did not trigger cytotoxic immune responses on mdx/HLA-A*0201 background, indicating that immune responses initiated in dystrophin defective mice depend on the gene transfer protocol.

The above-mentioned example proves that appropriate diseased HLA-A*0201 animal models could provide interesting clues on possible states of immune ignorance, susceptible to breakage after a secondary inflammatory challenges. To assay the occurrence of deleterious cellular responses in restored muscles, inflammatory agents, and/or antigenic peptide are to be injected, as ultimate tests for immunological safety. As in other gene therapy settings in which foreign sequences are transferred in immunocompetent hosts, the HLA-A*0201-restricted human dystrophin epitopes unraveled here (Ginhoux *et al*., 2003) are important tools to monitor the occurrence of immune responses in humans.

Finally, to circumvent the advent of unavoidable cellular responses, attempts have been conducted to shield vectors and transgenes from the immune response. The overall success of this strategy may depend on gene transfer modalities and on subtle combinations of purity, transduction efficiencies, and cell target specificities of the viral vectors used. Along this line, we initiated a study with a model transgene vectorized either with plasmid or AAV viral particles and showed that epitope engineering designed to mask an immunodominant sequence did generated in fact a set secondary rejection epitopes (Ginhoux *et al*., 2004). A Sisyphean task awaits therefore the gene therapists wishing to shield nonself epitopes recognized by the T cell repertoire in the host.

5. Conclusion

Humanized animal models are now highly desirable to explore the type of immune responses encountered and to define molecular determinants, which gear adaptive immune responses to transgene products. However, a lack of response in small animal models does not necessarily mean a lack of immunogenicity in humans. Nonspecific inflammatory conditions, which may differ from mice to humans and preexisting immune responses to vectors themselves may favor the initiation of immune responses to the transgene, much like the conversion of autoimmune T cell reactivity into overt autoimmune disease (Lang *et al*., 2005). So studying both the factors, which activate initial innate immune responses, and the molecular determinants present on transgenes will give important clues in the outcome of immune responses to gene transfer.

We hope *in fine* to induce long-lasting immune tolerance against foreign antigens expressed after a gene transfer. This can be tentatively achieved with regulatory T cells, which can blunt the initiation of immune responses and probably control inflammatory processes. In ideal circumstances, the establishment of mixed hematopoietic chimerism (Sykes, 2001) using the transgene of interest as a minor antigens should provide a strong therapeutic tolerance and obviate immune responses, by subduing all three heads of the Cerberus guardian.

Acknowledgments

We wish to thank Terry Partridge, Carole Masurier, David Gross, Nicolas Bertho, and Olivier Danos for critical reading of the manuscript, Florent Ginhoux and

Sabrina Turbant for privileged communications, and Huseyin Firat, Marylène Leboeuf, and François Lemonnier for constant support in the construction of HLA-A*0201 mouse models. Short Specialist Review

Gene transfer vectors as medicinal products: risks and benefits

Christian J. Buchholz and Klaus Cichutek
Paul-Ehrlich-Institut, Langen, Germany

The potential applications of gene therapy are plentifold, reaching from hereditary disease to acquired multifactorial disorders. The vector systems used for the transfer of the therapeutic gene into the patient are equally diverse including, for example, naked plasmid DNA as well as engineered viruses or genetically modified cells. Regarded as medicinal product when used in vivo, gene transfer medicinal products (GT-MPs) are unique in their extent of diversity and complexity not only relative to conventional chemical drugs but also relative to biological pharmaceuticals like recombinant proteins. They, therefore, equally challenge research and regulation.

Medicinal products, also termed drugs or medicines, are used for the treatment, diagnosis, or prevention of diseases in or on human subjects. Gene therapy and somatic cell therapy using genetically modified cells are best summarized under the term clinical gene transfer and involve the treatment of human subjects with GT-MPs. GT-MPs belong to the group of advanced biotechnology products for which testing provisions for marketing authorization have been specified in a legally binding document for the European Union. Marketing authorization for a GT-MP was recently granted for the first time worldwide in China for an adenoviral vector transferring the human p53 gene (Pearson *et al*., 2004). This product is being used for cancer treatment to restore the apoptosis pathway in p53-deficient tumor cells. Data showing clinical efficacy of this GT-MP have not been published.

GT-MPs have been used worldwide by the end of 2004 in almost 1000 clinical trials for in vivo diagnostics, prevention, or therapy. Most clinical gene transfer protocols are aimed at the treatment or prevention of cancer, cardio-vascular disease, infectious disease such as AIDS or monogeneic disorders, or at the prevention of infectious disease by vaccination. The vectors most often used ex vivo are MLV-derived gamma-retroviral vectors, whereas adenoviral and poxviral vectors have mostly been used in vivo. An increasing number of studies involves the use of nonviral vectors or naked DNA (refer to Table in (*see* Article 95, **Artificial self-assembling systems for gene therapy**, Volume 2).

More than 6000 human subjects have been treated with GT-MPs worldwide, most of them in the United States. Within Europe, probably the highest number of clinical gene transfer studies have been carried out in the United Kingdom and

in Germany. A few clinical trials have resulted so far in benefit for the patients involved (Table 1). It is becoming clear that each disease needs the development of a particular gene transfer method and regiment.

A particular case was the SCID-X1 trial performed by Alain Fischer's group at the Hospital Necker in Paris. This clinical trial drew most attention, reaching beyond the gene therapy field. From the same study, spectacular therapeutic effects were reported; however, novel, until then unexpected serious adverse reactions were also reported. SCID-X1 is caused by an inherited disorder, which occurs in the γ subunit of cytokine receptors encoded by the γc gene (Fischer *et al*., 2002). The γc polypeptide is used as a joint subunit in a number of interleukin receptors relevant for hematopoesis, including the receptors for IL-2, IL-4, IL-7, or IL-9. In children with SCID-X1, no functionally active cytokine receptor is found on the surface of lymphocyte precursor cells. This results in a complete failure of the cells to differentiate into T lymphocytes and natural killer (NK) cells. Thus, newborns with this congenital disorder lack the functional immune response to infectious diseases and are therefore forced to live under germ-free conditions. Conventional treatment of this disease requires allogeneic bone marrow transfer, if a suitable donor is available.

The gene therapy approach uses $CD34^+$ cells isolated from the patient's bone marrow, activated with a cytokine mixture, and then transduced with the γc gene by means of a conventional replication-incompetent retroviral vector derived from murine leukemia virus (Figure 1). The transduced cells are then reinfused into the patients. Until October 2002, when owing to the observed adverse events the trial was put on hold, 10 SCID-X1 patients had been treated. In nine patients, the gene therapy approach was able to provide a fully functional immune system during an

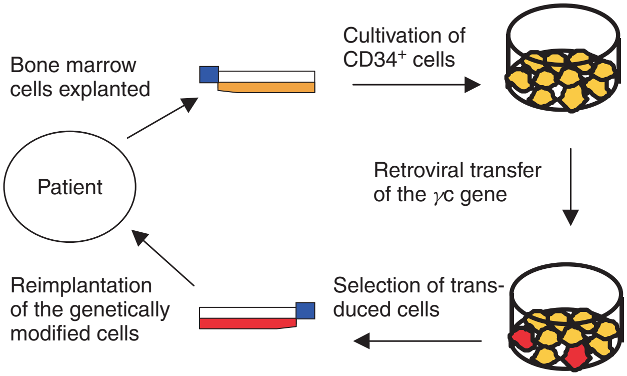

Figure 1 Gene therapy of SCID-X1. The first step is to purify, stimulate, and culture CD34$^+$ cells from the patient's bone marrow. The cells are then transduced with the γc gene using a retroviral vector, before they are reinfused into the patient

observation period of 3 years, partly even longer. For the affected children and their parents, this meant leading a normal life. The children could even tolerate vaccination against common infectious diseases.

However, about 30 months after treatment, two of the cured patients developed a T cell proliferative syndrome reminiscent of adult T cell leukemia showing a strong increase in the number of T lymphocytes, accompanied by splenomegaly and anemia. Owing to conventional chemotherapy, both patients recovered; one of them is currently in good health but the other patient died because of leukemia (Hacein-Bey-Abina *et al*., 2003). It is meanwhile commonly accepted that this disease was a result of chromosomal integration of the retroviral vector into the locus of the *Imo-2* gene, a known proto-oncogene, resulting in strong overexpression. The *Imo-2* gene encodes a transcription factor (rhombotin-2), which is upregulated during hematogenesis but usually not expressed in mature T lymphocytes. Expression of *Imo-2*, however, can lead to acute T cell leukemia (Herblot *et al*., 2000). Cofactors besides lmo-2 overexpression that contributed to the T cell proliferation might include the proliferative signals mediated through the transferred γc gene product, as well as familial predisposition to cancer or a chickenpox infection in one of the patients.

Thus, for the first time, insertional oncogenesis had manifested itself in a patient treated with retroviral vectors in the SCID-X1 clinical trial. Cancer development after retroviral gene transfer could therefore no longer be considered exclusively as a theoretical risk. As outlined below, it had immediate consequences for this and also for other clinical gene transfer studies using retroviral vectors.

In the European Union and also in the United States, national authorities are responsible for the registration of clinical trials. In the European Union, Directive 2001/20/EC lays down the rules for good clinical practice (GCP). According to this directive, which had to be transformed into national laws by May 2004, clinical trials using GT-MPs require approval by the competent national authority as well as a positive appraisal by an ethics committee. While the ethics committees, which are usually supported by advice from central gene therapy committees with expert

members that cover the different fields of gene therapy, focus on the ethical and medical acceptability of the study, the competent authorities evaluate the acceptability according to the current standards of science. For phase I clinical trials, which is by far the majority of all ongoing clinical gene therapy trials, this includes evaluation of preclinical data on quality, pharmacology, toxicology, and potency of the investigational drug.

The surveillance of clinical trials is another important task carried out by the national authorities. In the event of a suspected risk for enrolled patients or subjects, the competent authority can coordinate and exert suitable measures. Immediately when the reports about the severe adverse reactions in the SCID-X1 trials carried out in France became available, expert hearings took place not only in France but also in other countries such as Germany, the United Kingdom, and the United States to reconsider the safety of retroviral gene transfer. As an initial action (provision), the enrollment of further patients was put on hold at least for all studies using retroviral vectors for blood stem cell modification, in some countries for all clinical gene therapy studies using live retrovirally modified cells. The principal investigators, however, were given the opportunity to review the risk/benefit analysis on the basis of the new results, and to make the appropriate changes in the patient informed consent and the inclusion and exclusion criteria. All studies are currently being continued.

Especially, the risk/benefit analysis is of particular importance in this situation. For life-threatening disease where no alternative treatment is available, even the risk of leukemia may be justified. For example, treatment of patients suffering from chronic granulomatosis, who have a shortened life expectancy due to their congenital immune deficiency disorder, may be continued after changes in the protocol. On the other hand, pure marker gene studies using retroviral vectors without any direct benefit for the patient to be treated currently have a low likelihood of being authorized.

Gene transfer to skeletal muscle

Jeffrey S. Chamberlain
University of Washington School of Medicine, Seattle, WA, USA

1. Gene vectors for muscle tissues

Gene transfer into muscles can take a variety of forms, from delivery of whole genes, mini-gene expression cassettes, to oligonucleotides. Each of these types of genetic elements can, in theory, be delivered either as a simple DNA sequence, in the context of a plasmid vector, or embedded within a whole or modified viral genome. Oligonucleotides represent the simplest type of DNA to deliver, as they are easily synthesized and generally nontoxic. These sequences are typically short (15–100 bases) and do not encode an actual gene, but are intended to modify gene expression or directly target genetic mutations. Plasmids are also a simple method to transfer genes, and have the capacity to carry oligonucleotides, entire genes (or fragments thereof), or synthetic expression cassettes. Many applications of muscle gene therapy focus on the use of virally derived vectors to transfer genes or oligonucleotides. Viral vectors display the most efficient ability to target and enter muscle cells, so the majority of research on muscle gene therapy has used these vectors. However, viral vectors deliver not only the therapeutic nucleic acid sequence but also portions of the viral genome and/or virally encoded proteins. Consequently, a variety of specific modifications to the viral genomes involving deletion of some or all viral genes are typically used to increase the safety and to modulate the immunogenicity of these vectors. The viral vectors commonly used for direct muscle gene transfer include recombinant vectors derived from adenovirus and adeno-associated viruses.

2. Oligonucleotide transfer to muscle

Delivery of short oligonucleotides composed of DNA or DNA/RNA chimeras have been explored to modulate muscle gene expression or direct specific genomic DNA sequence modifications (mutagenesis) in muscle cells. The major application of this technology has been with the delivery of short DNA oligonucleotides that can bind to splice donor or acceptor sequences in muscle genes to trigger alternative splicing of RNA transcripts. This approach is a potentially powerful means to treat Duchenne muscular dystrophy (DMD), which typically arises from either a premature stop codon or by frameshifting mutations resulting from deletions or

splice site mutations that lead to exclusion of a particular exon or exon(s) from the encoded dystrophin mRNA (Lu *et al*., 2003b; van Deutekom *et al*., 2001). These oligonucleotides are delivered to myogenic cells in culture by conventional DNA transfection methods, or to intact muscles of animal models by direct injection. Oligonucleotides are generally nontoxic, do not elicit a cellular or humoral immune response, and they have a relatively short half-life, enabling discontinuation of an experiment or therapeutic intervention if unwarranted side effects develop. They can also be mass-produced using synthetic technologies. The disadvantages are that oligonucleotides display a relatively short half-life in vivo, on the order of weeks, which would require repetitive dosing to treat a chronic disorder. The other main disadvantage is that cellular uptake of oligonucleotides is inefficient, such that huge quantities are required, and a relatively low percentage of the musculature is targeted. To date, oligonucleotides have only been applied for localized delivery to individual muscles, although technological improvements, including delivery using viral vectors (below) may lead to methods for widespread delivery.

The second major application of oligonucleotides in muscle has been for the correction of genetic mutations. Several classes of oligonucleotides, including long (~50–200 bp) DNA oligonucleotides and chimeric DNA/RNA oligonucleotides (chimeroplasts) can lead to targeting of specific genomic sequences and subsequent repair or conversion of a mutant or mismatched base to the corresponding sequence of the oligonucleotide (Bertoni and Rando, 2002). Through mechanisms that are largely undefined, base pairing between the mutant genomic DNA sequence and the oligonucleotide can lead to correction of the mutation in the genomic DNA. The theoretical advantage of this approach is that it combines the safety factor of nonviral vectors with a method to permanently correct a genetic mutation. The disadvantage is that to date this approach has proved to be inefficient, with an ability to correct at most ~1% of the mutant genomes near the injection site.

3. Plasmids for gene transfer to muscle

Plasmids were the first vectors used to deliver genes to muscles and are still in wide use. In theory, any gene or expression cassette can be inserted into a plasmid for delivery, so these vectors can accommodate large genes. However, the efficiency of gene transfer seems to drop with increasing plasmid size. Moderate levels of transduction can be obtained by direct intramuscular injection of plasmids, although efficiencies vary with the age of the animal, the species, and the method of injection (Zhang *et al*., 2004a). Plasmid expression vectors enable one to choose a particular promoter, such as a muscle-specific promoter, to drive gene expressions (Ferrer *et al*., 2000). Although intramuscular injections do not result in widespread muscle gene transfer, intravenous and intravascular methods have been developed using high pressure and volume injections that enable wider gene transfer to numerous muscles in a limb (Zhang *et al*., 2004b). Increased muscle transduction can be achieved by combining direct injection with the use of electroporation, and injection of block polymers (pluronics), or microbubbles in combination with ultrasound (Lu *et al*., 2003a). To date the best transfer efficiencies are between 10 and 50% of the myofibers in limb muscles (Zhang *et al*., 2004b). This promising method has

already been used in a phase 1 human clinical trial for DMD without adverse events, although little gene expression was detected with the doses used (Romero *et al*., 2002).

4. Adenoviral vectors

Vectors derived from adenoviruses were the first viral vectors used for muscle gene transfer (*see* Article 97, **Adeno-associated viral vectors: depend(o)ble stability**, Volume 2). Adenoviral (Ad) vectors are deleted for the E1 region of the viral genome, rendering them largely replication-defective. These conventional Ad vector have a cloning capacity of about 7 kb and are relatively efficient at muscle gene transfer, although the efficiency drops with increasing muscle maturation due to loss of the Ad receptor CAR (Nalbantoglu *et al*., 2001). Nonetheless, dystrophic and regenerating muscles of adult animals can still be efficiently targeted (DelloRusso *et al*., 2002). The major drawback of Ad vectors is their propensity to elicit potent cellular and innate immune responses, due primarily to leaky viral gene expression and effects of the capsid proteins, respectively. Improved vectors with reduced viral gene expression and lower replication capacity have been developed by deletion of additional viral genes, primarily the *E2b* and the *E4* genes (Barjot *et al*., 2002). The best Ad vectors for muscle gene transfer are fully deleted, or gutted Ad vectors, that lack all viral genes (DelloRusso *et al*., 2002; Chen *et al*., 1997). These vectors are more difficult to grow, and require a helper Ad vector that is removed from the vector preparations by Cre-recombinase-mediated destruction of the helper virus followed by CsCl density gradient centrifugation (Parks *et al*., 1996). Gutted Ad vectors can carry genes up to 30 kb in size, and have been used to efficiently deliver the full-length 14-kb dystrophin cDNA to adult *mdx* mice, a model for DMD (DelloRusso *et al*., 2002; Chen *et al*., 1997). Ad vector delivery has been limited to intramuscular injection, as they appear too large to traverse the vascular endothelial barrier lining blood vessels (Gregorevic *et al*., 2004a; Greelish *et al*., 1999). However, the residual ability of these vectors to elicit an innate immune response coupled with their difficult production requirements have greatly limited their application in human clinical trials. These vectors are still a good choice for gene transfer in culture, and are still being developed owing to their large cloning capacity.

5. Adeno-associated viral (AAV) vectors

The most promising vectors for muscle gene transfer currently are derived from adeno-associated viruses (rAAV) (Gregorevic *et al*., 2004b; *see also* Article 96, **Adenovirus vectors**, Volume 2). AAV-derived vectors typically do not elicit significant innate or cellular immune responses, at least as assayed in normal mice, and have been shown to support gene expression for at least 4 years following delivery to muscles of mice, dogs, and nonhuman primates (Xiao *et al*., 1996; Manno *et al*., 2003). In dystrophic muscle, however, some vectors expressing foreign transgenes elicit a cellular immune response when the transgene is expressed

from a ubiquitously active promoter, such as CMV, but not when expressed from a muscle-specific promoter, such as MCK (Yuasa *et al*., 2002). The major limitation of rAAV vectors is their small, 5 kb cloning capacity. For large genes, such as dystrophin, this limited cloning capacity has been partially addressed by the development of truncated, yet highly functional micro-dystrophin cDNAs expressed from small muscle-specific promoters (Wang *et al*., 2000; Harper *et al*., 2002). Delivery of micro-dystrophins to dystrophic *mdx* mice has been shown to prevent and partially reverse dystrophic pathologies in mice. Nine different serotypes of AAV have been tested for the ability to target a variety of different tissues, and vectors derived from AAV1, 5, and 6 have shown the best ability to transduce muscle (Gao *et al*., 2004; Blankinship *et al*., 2004). These vectors are easily delivered by direct intramuscular injection. Unlike Ad vectors, which begin expressing within 24 h of injection, rAAV vectors take 2–5 weeks to achieve maximal transgene transcription (Malik *et al*., 2000; Blankinship *et al*., 2004). The small size of rAAV vectors has also proven to be a great advantage in the development of methods for whole-body targeting of muscle tissues. Vectors based on AAV6 have been shown capable of transducing all the striated muscles in adult mice with various transgenes, including micro-dystrophins, when injected directly into the tail vein (Gregorevic *et al*., 2004a). Other methods have been used for targeting muscles of individual limbs (Greelish *et al*., 1999). These approaches represent potentially powerful methods for gene therapy of a variety of muscle disorders. Vectors based on rAAV may also be useful for delivering other expression cassettes, including antisense oligonucleotides, which was recently shown to be a promising approach for DMD (Goyenvalle *et al*., 2004). rAAV vectors are easily grown in cell cultures by a 2-plasmid cotransfection system (Blankinship *et al*., 2004). Unlike Ad vectors, rAAV vectors typically do not work well for gene transfer in cell culture systems.

6. Conclusions

Numerous vectors are available for gene transfer to muscle. The choice of vectors and delivery route is dependent on the specific application. AAV vectors offer numerous advantages over other vector systems, as they are easily prepared at high titer, they evoke minimal immune reactions, and they can transduce muscles body-wide. However, AAV vectors have a limited cloning capacity and do not work well in cell culture. Oligonucleotides and plasmids work well in cell culture, are not limited by a vector cloning capacity and seem to have the safest potential in avoiding immune reactions. Ad vectors have the greatest cloning capacity and work well in cell culture, but are much more cumbersome to prepare in forms that minimize immune reactions. For basic research studies and for preclinical studies, these various vectors offer a wide choice in transferring genes to myogenic cells. Nonetheless, further work is needed to adapt any of these vector systems toward a therapy for human neuromuscular disorders, and other vector systems as yet poorly studied may someday prove to be better than the current vectors. Currently, plasmids, oligonucleotides, and rAAV vectors expressing micro-dystrophins are in various stages of being tested in human clinical trials for DMD. It is hoped that at least one of these systems will have an important clinical impact on this and other

muscle disorders (*see* Article 100, **Gene transfer vectors as medicinal products: risks and benefits**, Volume 2).

Basic Techniques and Approaches

Gene transfer to the liver

Katherine Parker Ponder
University of Washington School of Medicine, St. Louis, MO, USA

The liver is an important target for gene therapy. First, many genetic diseases could be corrected with liver-directed gene therapy. These include deficiencies in metabolic enzymes such as phenylketonuria, deficiencies in blood proteins such as hemophilia, lysosomal storage diseases, infectious diseases such as hepatitis B or C, or liver tumors. Second, hepatocytes have direct contact with blood, allowing the vector to reach most cells with a simple portal vein, hepatic artery, or intravenous injection, which is the mode of delivery currently used in most studies. Third, hepatocytes are long-lived, and are what replicate in response to normal growth or liver injury. This makes it possible to obtain long-term correction after the transfer into fetal or newborn animals if the vector integrates into the chromosome.

Substantial success has been achieved in the liver using retroviral, adenovirus-associated virus (AAV), adenoviral, and plasmid vectors for gene therapy (Kren *et al*., 2002; Thomas *et al*., 2003; VandenDriessche *et al*., 2003). The best long-term expression has been achieved using vectors that utilize a promoter that is normally expressed in the liver, such as the human α1-antitrypsin promoter. In contrast, most viral promoters such as the cytomegalovirus (CMV) promoter have attenuated substantially over time. Gamma-retroviral vectors (Kren *et al*., 2002; Thomas *et al*., 2003; VandenDriessche *et al*., 2003), which only transduce dividing cells, have transferred genes into small and large animals in the newborn period, when hepatocytes are replicating because of the rapid growth. This approach has reduced clinical manifestations of hemophilia A and B, and mucopolysaccharidosis VII in mouse and canine models. This neonatal approach has additional advantages, as it usually induces tolerance to otherwise immunogenic proteins, and corrects the genetic defect earlier. In adults, delivery of gamma-retroviral vectors has required induction of hepatocyte replication with a hepatic growth factor or liver damage. Although effective in mice with hemophilia or thrombophilia, this approach has not yet been applied in large-animal models. Lenti-retroviral vectors can transduce nondividing cells, and have delivered genes to adult rodents without induction of hepatocyte replication. Lenti-retroviral vectors have reduced clinical manifestations in mice with hemophilia, but have not yet been applied in large animals. A major concern of retroviral vectors is the risk of insertional mutagenesis, in which adjacent genes might be activated by enhancer elements of the vector. Indeed, insertional mutagenesis contributed to the leukemias that developed after bone marrow–directed gene therapy for severe combined immunodeficiency, although

other factors almost certainly contributed. To date, no tumors have developed in mice or dogs after liver-directed gene therapy with retroviral vectors. Thus, retroviral vectors show substantial promise for gene therapy, although further safety evaluation needs to be performed.

AAV vectors can transduce nonreplicating hepatocytes of small and large animals in adults. They are primarily maintained in an episomal form although a small fraction of the sequences integrate into the chromosome (Grimm and Kay, 2003). AAV vectors have resulted in amelioration of a number of genetic diseases in mice, and have reduced bleeding in dogs with hemophilia B. One problem with AAV vectors is their small capacity of only ~5 kb of total sequence. This has made it difficult to achieve high levels of expression of large genes such as the Factor VIII gene that is deficient in hemophilia A. AAV vectors have also transduced hepatocytes of newborn mice with mucopolysaccharidosis VII. The substantial fall in expression that occurred during normal growth was likely due to the lack of integration of most copies. There is currently a clinical trial using an AAV2 vector to treat humans with hemophilia B. Although patients who received the highest dose had expression for about a month, this fell to undetectable levels thereafter, which was likely due to cytotoxic T lymphocyte responses against cells that contain Factor IX or the AAV capsid proteins. If the immune response was against the AAV2 capsid proteins, this might be avoided by generating vectors with capsid proteins from other serotypes, some of which do not normally infect humans but are efficient at transferring genes into the livers of animals. Thus, AAV vectors show substantial promise for gene therapy, although existing immunity to AAV2 capsid proteins may be problematic, and they have some risk of insertional mutagenesis.

Adenoviral vectors have a large capacity and can transduce nondividing hepatocytes extremely efficiently (Kren *et al*., 2002; Thomas *et al*., 2003; VandenDriessche *et al*., 2003). They have resulted in long-term expression of several therapeutic proteins in rodents. However, stable expression has not been achieved in most large-animal studies, which may be due to the failure to integrate. An additional problem with adenoviral vectors is the induction of inflammatory responses, which was likely responsible for the death of a patient with a urea cycle disorder. Development of adenoviral vectors that do not contain any viral genes has not eliminated this problem, although reduction of the dose with a strong liver-specific promoter has been effective. The role of adenoviral vectors in gene therapy for nonmalignant disorders is uncertain, as the instability and the inflammatory responses evoked are major hurdles.

Plasmid vectors have transferred genes into the liver and achieved therapeutic levels of expression (Kren *et al*., 2002). Stable expression has been achieved in rodents by cotransfer of a transposase that results in the integration of the therapeutic gene into the chromosome of hepatocytes, or by using plasmids that are maintained long-term extrachromosomally. The major problem with plasmid-based systems is that it has been difficult to achieve high-level transfer into hepatocytes. The most efficient method is to use a high-pressure injection, which has substantial toxicity. Use of simple plasmid vectors for gene therapy will require identification of an efficient and nontoxic method for getting them into hepatocytes. Alternatively, replication-deficient SV40 vectors have transferred circular DNA molecules into

the liver and maintained expression long-term, although these vectors still contain some viral genes that might provoke cytotoxic T lymphocyte responses against transduced cells in some species. Thus, plasmid-based vectors show promise for gene therapy, although delivery to the liver is a problem, and vectors that result in random integration will also have a risk of insertional mutagenesis.

Gene transfer to the skin

Laurent Gagnoux-Palacios, Flavia Spirito and Guerrino Meneguzzi
University of Nice-Sophia Antipolis, Nice, France

1. Introduction

The skin is the physical barrier that preserves the body from environmental aggressions. The outer compartment of this organ, the epidermis, is a continuously renewing tissue produced by a proliferative basal layer of keratinocytes generated by transiently amplifying cells, which derive from epithelial stem cells. Differentiating basal keratinocytes migrate into the suprabasal cell layer and enter a stepwise process of keratinization and lipogenesis that defines the distinct layers of the epidermis: the spinous, granular, and corneum stratum. The stratum corneum is made of dead, terminally differentiated keratinocytes, and assumes defense functions including barrier to water permeability, penetration of xenobiotics, and parasitic infection. The epidermis is anchored to the dermis, the connective tissue component of the skin, which in addition to the large populations of fibroblasts that produce and organize the extracellular matrix, contains epithelial, vascular, neural, and haematopoietic cells. In association with the antigen-presenting cells (Langerhans and T-cells lymphocytes) of the epidermis, the macrophages, neutrophils, and lymphocytes of the dermis provide high levels of local immune surveillance. Thus, gene transfer to the skin is faced to an outer barrier, the stratum corneum, which protects the target living cells of the inner epidermis and dermis.

The skin is an optimal target organ for gene transfer because of its accessibility to manipulations and the ease with which the epidermal and dermal cells are biopsied, expanded in culture, genetically manipulated, and grafted back to the patients, following well-established procedures. Besides applications in the correction of genodermatosis, genetic manipulations of the skin have potential use in vaccination against cancer and infectious diseases. Engineered keratinocytes are also potential bioreactors for the production of locally and systemically active polypeptides with a therapeutic interest in the treatment of hormonal and metabolic disorders affecting other organs. An additional advantage over the other organs is that any adverse effect of genetic manipulations on the skin is easily monitored and the involved tissue readily removed.

A range of techniques for the introduction of recombinant DNA into the skin has been developed for *in vivo* and *ex vivo* gene transfer. In the *in vivo* approach, the DNA is directly administered to the skin, while *ex vivo* gene transfer requires

introduction of the desired gene into cells harvested from skin biopsies and generation of self-renewing tissue transplantable back to the donor. Technical achievements in gene transfer combined with the sophisticated methods of skin grafting make the *ex vivo* approach most attractive, despite its limited application to the few cell types for which culture conditions and transplantation techniques are well defined and the fact that the viability of the grafted cells, the need for multiple surgical procedures, and the risk of scarring may hamper the clinical applicability. Alternative *in vivo* systems require much less biotechnological expertise and effort. However, the efficiency of *in vivo* gene transfer is generally low and associated with a transient expression of the therapeutic gene. Most of the *ex vivo* and *in vivo* strategies rely on the use of either viral or nonviral vectors designed by specific therapeutic needs: transient transgene expression is adapted in tissue repair, vaccination, or anticancer treatments, while permanent gene expression, possibly regulated by inducible promoters, is required for the permanent correction of inherited and acquired conditions.

1.1. *Viral vectors*

Recombinant viruses have been the most successful methods for gene transfer and clinical applications because the manipulation of the viral genomes is relatively easy and controllable. Various viral systems have been adapted to develop high efficiency gene transfer to the skin. These include replication-defective retroviruses (*see* Article 98, **Retro/lentiviral vectors**, Volume 2) and adenovirus (*see* Article 96, **Adenovirus vectors**, Volume 2) and recombinant adeno-associated viruses (AAV) (*see* Article 97, **Adeno-associated viral vectors: depend(o)ble stability**, Volume 2).

Retroviral vectors based on murine leukaemia virus (MLV) are currently used to achieve long-term expression of a foreign gene in the skin. The major advantages of these vectors include their capacity of transferring genes at high efficiency, and to permanently integrate them into the host cell chromosomes, which assures a stable and efficient expression. Since integration of MLV-based vectors requires host cell division, these vectors are conveniently used both to transfect cultured keratinocytes and to target proliferative cells in regenerating tissue *in vivo*. Disadvantages of retroviral gene transfer are represented by the limited size of the transferred DNA, the complexity of the methods for virus production, the relatively low titers of the viral suspensions, the limited types of proliferating skin cells that can be efficiently targeted, and the lack of control on integration into the host genome. Permanent *ex vivo* transduction of keratinocyte stem cells with a low number of integration events is achieved by integrating the producer cells into the lethally irradiated feeder for primary keratinocytes (Dellambra *et al*., 1998). The development of retroviral MSC vectors has allowed highly efficient *ex vivo* transduction of epithelial stem cells by direct transduction with purified virus. The recent construction of retroviral vectors based on lentiviruses, which yield high titers of infectious virions and integrate into the genome of nonproliferating cells, has overcome the major constraints in MLV retroviral gene transfer to the skin. Lentiviral vectors have been successfully used to efficiently transfer relatively

large cDNAs in cultured keratinocyte with sustained and stable expression of the transgene after transplantation of the engineered cells *in vivo* (Chen *et al*., 2002). Long-term transduction of mouse keratinocytes by a retroviral vector has also been demonstrated *in vivo* after mechanical abrasion to remove the interfollicular epithelium and induce re-epithelialization from proliferating stem cells located in the hair follicles, and by intradermal injections of viral particles (Hengge *et al*., 1995; Ghazizadeh *et al*., 1999). However, administration of the virus by injections between the scab and the regenerating epithelium hampers the quantification of the material delivered to the cells and it is technically too complex for clinical applications. Intradermal injection results in transduction of all the cell populations close to the inoculation site, including endothelial and dendritic cells, which causes undesired side effects. The possible activation of proto-oncogenes consequent to integration into the host genome implies a risk of cancerization of the transduced cells that must be considered. Therefore, the choice of the transduction protocols and retroviral vectors should favor procedures that limit the number of the genomic integrations of the therapeutic gene.

Recombinant adenoviral vectors provide transient and highly efficient gene transfer, and because of their inability to integrate into the host genome, they represent a useful alternative to retroviral gene transfer when the permanent expression of the transgene in the skin is not required. Their ability to infect nondividing cells makes adenoviruses particularly adapted for *in vivo* transduction of slowly dividing or differentiated cells such as melanocytes, Langherans cells, and suprabasal keratinocytes. However, the interest of adenoviral vectors for skin gene therapy is limited because the most efficient constructs induce a transient and dose-dependent inflammatory reaction to the viral proteins that is enhanced when repeated treatments are required.

Safety, an elevated physical stability, and lack of immunogenicity are the interesting properties of recombinant AAV vectors. However, AAV vectors transduce dermal fibroblasts inefficiently and transduction of keratinocytes is poorly documented. In our hands, primary keratinocyte cell cultures enriched in stem cells are resistant to the AAV infection, whereas efficient transduction with persistent expression of the transgene was observed with keratinocytes either senescent or immortalized. Exploitability of AAV vectors in skin gene therapy is therefore questionable.

1.2. Nonviral gene transfer

This is based on technologies involving easy production and direct application of the genetic material *in vivo* and *in vitro* (*see* Article 95, **Artificial self-assembling systems for gene therapy**, Volume 2). Most of nonviral vectors are synthetic means of encapsulating transgenic DNA until it reaches the cellular target. These vectors are safe to prepare, suitable for large-scale manufacturing procedures, and the risk of pathological and immunological complications is negligible. This approach, however, suffers from inefficient transfer and transitory expression of the transgene that does not integrate into the host genome. For *in vivo* delivery, the therapeutic DNA must overcome the epidermal barrier and reach the underlying target cells. To facilitate penetration into the skin, various techniques (prolonged occlusion,

electrically assisted delivery by iontophoresis or electroporation, sonography) based on the disruption or alteration of the stratum corneum have been devised but they remain unapplicable for clinical use. Lipofection has been used *in vivo* and in clinical trials, but the advantage of liposomes in terms of no constraint on the size of the transgene, the nontoxicity, and the possibility of multiple applications is counterbalanced by the low frequency of stable transfection, the stability, and the cost of the reagents. The delivery of the transgene is efficient to hair follicles, which may constitute the ideal target for this application. Direct injection of DNA has low potential for biohazardous risk but remains inefficient. Introduction of naked plasmid DNA into the superficial dermis by single inoculation leads to transient transgene expression concentrated in the layers of the epidermis overlying the injection site and low expression in the injected connective tissue. Efficiency can be enhanced by multiple microinoculations (microseeding) into the skin or by particle bombardment (ballistic gene transfer). The ballistic microprojectiles are made of small gold particles coated with DNA that are projected at high speed by a gene gun. This technique has been successfully used in various animal models, but the transgene expression remains transient (5 to 30 days) and efficiency is elevated only when the basal keratinocytes of the epidermis are targeted.

Because keratinocytes and fibroblasts are easily expanded in tissue culture, relatively efficient gene transfer can be achieved *ex vivo* using systems that involve insertion of the desired gene into nonviral episomal expression vectors containing specific regulatory and selection elements, and following the procedures currently used to transfect the mammalian cells. These include DNA-mediated transfection by methods such as calcium phosphate precipitation, DEAE-dextran transfection, polybrene-dimethyl sulfoxide shock, direct microinjection, jet injection or electroporation of pure plasmid DNA or DNA complexed with surface-receptors ligands, cationic liposomes, or ballistic microprojectiles. Cell toxicity or induction of keratinocyte differentiation may constitute a hindering side effect in a number of these methods. All these nonviral transfer systems permit only transient gene expression, because efficient host integration does not occur, except in transposon-based plasmids. For instance, the phage ϕC31 integrase mediates integration in the human cell DNA at endogenous attachment sites of extrachromosomal vectors carrying a therapeutic cDNA (Ortiz-Urda *et al*., 2002). However, the integration frequency is low, just above the background of random integration, so that observation of the curative effect requires the enrichment of the recipient keratinocytes using a selectable gene. Thus, the ideal gene transfer system that reliably permits high efficiency, safe, and prolonged expression of a therapeutic gene is still missing. At the current state, the nonviral technology is unsuitable for *in vivo* gene therapy.

Direct DNA injection into the skin yields a protective immune response. The nature of the genetic immunization depends on the technique used (injection of naked DNA or bombardment of DNA-coated microprojectiles), the amount of DNA, and the site of immunization. DNA vaccines remain an attractive mode of treatment and investigation in gene expression technology and in enhancing various aspects of adjuvant effects. The immune system of the skin is stimulated even by low expression of exogenous gene products directly introduced in Langerhans cells and dermal dendritic cells; therefore, expression of an exogenous transgene is expected to elicit an immune response against the genetically modified

cells. Immune responses can also be elicited by antigens generated by the secretion or processing of recombinant polypeptides synthesized by *ex vivo* transduced keratinocytes, with destruction of the genetically manipulated cells. Because any transgene product containing novel epitopes is a potential target of the host immune response, deep investigations are necessary to evaluate the host tolerance to each gene product delivered to the skin and assess the potential setbacks in setting up human clinical trials (Ghazizadeh *et al.*, 2003).

Basic Techniques and Approaches

Control of transgene expression in mammalian cells

Beat P. Kramer and Martin Fussenegger
Institute of Chemical and Bio-Engineering, Zurich, Switzerland

1. Introduction

Since most genetic disorders result from deregulated transcription or mutated genes, current gene therapy initiatives focus on complementation of genetic defects using adjustable expression of therapeutic transgenes to ensure precise titration into the therapeutic window, coordination with patient-specific disease dynamics, and termination of therapeutic interventions. Ideal conditional therapeutic transcription interventions require complex systems that (1) are of heterologous origin to ensure an interference-free operation, (2) enable seamless integration into regulatory networks of target cells, (3) exhibit low immunogenicity, (4) provide high-level expression under induced and low basal expression under repressed conditions, (5) show adjustability to intermediate levels over a wide range of inducer concentrations, (6) are responsive to a bioavailable inducer including clinically licensed small-molecule drugs, other inert molecules, or any specific well-tolerated physical condition, (7) exhibit high compatibility with approved viral and nonviral gene transfer technologies, (8) support configurations to restrict interventions to specific tissues or disease foci, and (9) are amenable to compact genetic design to limit pleiotropic effects associated with repeated molecular intervention on the patient's chromosome.

Generic design concepts of most advanced transcription control systems include artificial transcription-modulating (fusion) proteins that bind or assemble at specific target promoters in a small molecule-dependent manner or at specific physical conditions.

2. Antibiotic-responsive gene regulation systems

Antibiotic-responsive gene regulation systems are derived from prokaryotic antibiotic response regulators evolved to coordinate resistance to specific classes of antibiotics. A protein represses a resistance gene until its release from the target promoter following binding of a specific antibiotic. Such antibiotic-responsive protein–DNA interactions have successfully been assembled in three different configurations for conditional transgene transcription in mammalian cells: (1) Fusion of

the bacterial antibiotic resistance gene repressor to a generic transactivation domain creates an antibiotic-dependent transactivator, which, in the absence of regulating antibiotics, binds and activates chimeric promoters containing transactivator-specific (tandem) operator modules 5′ of a minimal eukaryotic promoter (Gossen and Bujard, 1992; Fussenegger *et al*., 2000a; Weber *et al*., 2002). (2) The aforementioned transactivator can be mutated to enable reverse antibiotic-dependent binding, resulting in dose-dependent transgene induction in the presence of regulating antibiotics (Gossen *et al*., 1995). (3) The bacterial antibiotic resistance gene repressor bound to its cognate operator may repress transcription from 5′-located mammalian promoters. The antibiotic-induced repressor release then correlates with increased transgene transcription (Fussenegger *et al*., 2000a; Yao *et al*., 1998; Weber *et al*., 2002). Three different transcription control systems responsive to tetracyclines (Gossen and Bujard, 1992), streptogramins (Fussenegger *et al*., 2000b), and macrolides (Weber *et al*., 2002) have been developed. Antibiotic-responsive gene regulation systems comply with ideal systems at a high standard. Yet, potential immunogenicity of bacterial components, tissue-specific accumulation, and/or promotion of antibiotic resistance will remain ongoing challenges for clinical implementation (Darteil *et al*., 2002).

3. Hormone-inducible gene expression

Lipophilic hormones are key players of intercellular communication in higher eukaryotes. They freely cross cell membranes, bind intracellular receptors, and modulate target gene expression following nuclear translocation. The generic design concept for hormone-inducible gene regulation systems consists of fusing the hormone-binding domain of a hormone receptor to a heterologous DNA-binding module and optionally to a transactivation/transsilencing moiety. This chimeric hormone receptor will initiate/repress transcription from target promoters equipped with DNA-binding domain-specific operator modules in the presence of regulating hormones. The use of human hormone receptor mutants specific for endogenous hormone agonists is expected to enable increased immunocompatibility without interfering with endogenous hormone regulatory networks. Yet, some hormone agonists exhibit a major clinical impact. Three hormone-inducible transcription control systems responsive to estrogen (Braselmann *et al*., 1993), the progesterone antagonist mifepristone (Wang *et al*., 1994), and the insect moulting hormone ecdysone (No *et al*., 1996) have been constructed, and are continuously improved for human compatibility.

4. Dimerizer-regulated gene expression

Chemically induced dimerization (CID) is a phenomenon by which two proteins (hetero)dimerize in the presence of a molecule. The most prominent heterodimerizer is the immunosuppressive agent rapamycin, which unites FKBP (FK506-binding protein) and FRAP (FKBP rapamycin-associated protein), thus impairing cell cycle regulatory networks involved in T cell expansion. Rapamycin-inducible

heterodimerization of FKBP fused to artificial DNA-binding domains and FRAP to a transactivation domain reconstitutes a chimeric transactivator that initiates transcription from target promoters containing specific operator modules. In order to alleviate cosuppression of the immune system when rapamycin-based CID transcription control is in action, protein engineering initiatives to alter FKBP and FRAB's specificities for a nontoxic, clinically inert molecule are promising and may secure a clinical future of this technology (Pollock and Clackson, 2002).

5. Systems of the future

Despite quantitative differences in regulation performance, most aforementioned transcription control systems qualify for clinical implementation. However, improvement of immunocompatibility and tolerability of inducers remain future challenges. Current systems based on prokaryotic antibiotic resistance operons promise specific regulation by clinically licensed molecules, but are compromised by the use of bacterial epitopes and long-term accumulation of antibiotics in various tissues of the body. Hormone- and CID-responsive transgene control systems can be optimally humanized, yet remain limited by pleiotropic and other side effects of their inducing agents. Even when using artificial molecule-protein interactions, immunocompatibility and side effects of designer molecules remain imminent concerns. On the way toward ideal transgene regulation modalities, a variety of strategies have been designed, which promise important improvements over existing technologies: (1) construction of transcription modulators responsive to clinically inert compounds, temperature, light, and dynamic electromagnetic fields, (2) systems responsive to specific nucleic acids, and (3) epigenetic gene networks.

Prokaryotes manage inter- and intrapopulation communication by quorum-sensing molecules, which bind to receptors in target cells and initiate specific regulon switches by modulating the receptors affinity to cognate promoters (Bassler, 2002). Systems derived from bacterial, quorum-sensing regulatory networks are expected to be of particular interest since many regulating molecules of commensal prokaryotic populations have a long history of human-prokaryotic coevolution. Following the generic design principle of antibiotic-adjustable transcription control modalities, bacterial cross talk systems responsive to butyrolactones have been successfully validated in mice without signs suggestive of inducer-related side effects (Weber *et al*., 2003b; Neddermann *et al*., 2003).

Throughout the development of eukaryotes, production of ribosomal proteins (rp) is regulated at the translational level. Translation control is mediated by a terminal oligopyrimidine element (TOP) present in the 5′ untranslated region of rp-encoding proteins. TOP elements adopt a translation-prohibitive secondary structure, which is resolved upon binding of a specific cellular nucleic acid–binding protein (CNBP). TOP-complementary nucleic acids interfere with the translation-promoting TOP–CNBP interaction and so repress top-tagged mRNAs in a dose-dependent manner (Schlatter and Fussenegger, 2003).

Two low-temperature-inducible mammalian gene regulation systems have been designed capitalizing on (1) a heat-labile alphaviral replicase that transcribes target genes driven by subgenomic promoters only at permissive temperatures (Boorsma

et al., 2000) and (2) a thermosensor managing heat-shock response in *Streptomyces albus* (Weber *et al*., 2003a). Owing to dominant environmental conditions, clinical implementation of temperature-controlled expression technology would require local temperature control by a Pelletier element.

Light-inducible gene regulation may represent an alternative to temperature-based control. A recently discovered photosensitive plant protein heterodimerizes with a partner protein following exposure to the cofactor phynocynanobilin and transient red and far-red light pulses. Assembly of these heterodimerizing proteins analogous to CID systems enabled light-inducible transgene expression in yeast (Shimizu-Sato *et al*., 2002). Owing to limited tissue penetration, nonvisible electromagnetic fields have come into the limelight of the gene control community, but these systems are at best in the discovery stage: (1) several electromagnetic field response elements (EMRE) have been discovered in humans (Lin *et al*., 2001; Rubenstrunk *et al*., 2003) and (2) radio-frequency magnetic fields were shown to remotely control hybridization of oligonucleotides linked to gold nanoparticles (Hamad-Schifferli *et al*., 2002).

Throughout multicellular systems, cell identity is maintained by epigenetic regulation circuits, which imprint transient morphogen gradients during early embryogenesis by locking the transcriptome of adult cells in a cell phenotype-specific manner. By combining two repressors, which control each other's expression, an epigenetic circuitry able to switch between two stable expression states by transient addition of two inducers has been pioneered (Kramer *et al*., 2004). Owing to transient administration of regulating agents, long-term side effects will be eliminated.

6. Conclusions

Much like drug dosing is the key parameter in modern molecular medicine since Paracelsus' statement that "the dose makes the poison", gene expression dosing will be of central importance for next-generation gene therapy and tissue engineering initiatives. Capitalizing on achievements accumulated for over a decade, conditional transcription control of therapeutic transgenes stands now on the threshold to a clinical reality. With the first transcription control units being assembled into regulatory gene networks and prototype epigenetic gene switches being designed for mammalian cells, the future for multigene-based therapeutic interventions in regulatory networks of patients' cells has just begun.

Introductory Review

Eukaryotic genomics

Mark D. Adams
Case Western Reserve University, Cleveland, OH, USA

1. Introduction

In the early 1990s, a plethora of strategies for genome sequencing were proposed as part of the initial phases of the Human Genome Project (HGP). Each strategy relied to varying extents on three types of maps: (1) genetic and radiation hybrid maps consist of sequence tagged site (STS) markers of known order throughout the genome that can be used as landmarks (*see* Article 14, **The construction and use of radiation hybrid maps in genomic research**, Volume 3 and Article 15, **Linkage mapping**, Volume 3), (2) physical maps are composed of overlapping cloned regions of the genome that are tied to the landmark maps and can be used as the physical source of DNA for sequencing a segment of the genome (*see* Article 9, **Genome mapping overview**, Volume 3 and Article 18, **Fingerprint mapping**, Volume 3), and (3) the sequence map, which is the genome sequence itself. So many factors underlie these interconnected maps that the initial plan for the HGP chose to defer decision making on many aspects of the latter two maps until they could be developed together as technology for collecting DNA sequence improved and lessons had been learned from model organism sequencing projects.

By the end of the 1990s, genome sequences were in hand for *Saccharomyces cerevisiae* (Goffeau *et al*., 1996; Goffeau *et al*., 1997), *Caenorhabditis elegans* (*C. elegans* Consortium, 1998), and several bacteria and archaea. Sequencing technology had improved dramatically and a few large laboratories were running scores of automated DNA sequencers and producing thousands of high-quality DNA sequence lanes per day. With the introduction of 96-channel capillary sequencers in 1998, the rush was on to capitalize on even greater sequencing capacity to get the human genome sequence done. Two strategies were chosen by Celera Genomics and the International Human Genome Sequencing consortium. These two strategies and several blends between them continue to be used for the sequencing of other eukaryotic genomes. A brief analysis of the “whole-genome shotgun” and “hierarchical shotgun” method will provide an introduction to this section on Genome Sequencing.

2. Sequencing and assembly approaches

2.1. Hierarchical shotgun

Traditional genome-sequencing methods (Blattner, *et al*., 1997, Goffeau, *et al*., 1997, *C. elegans* Consortium, 1998) have relied on making a carefully constructed map of genome subclones, sequencing each subclone, and then reassembling the complete genome by piecing together the subclone sequences. The maps are generally constructed by a combination of marker-driven methods (probing a subclone library with short sequences such as STSs) and fingerprint methods (restriction digest patterns of clones are compared to one another to identify overlapping clones). A set of subclones is then chosen for sequencing on the basis of selecting the smallest number of clones that reliably covers the genome. The advantage of this approach, termed "hierarchical shotgun sequencing", is that there are several opportunities for checking the quality of the map as it progresses (i.e., do the fingerprint and marker order data agree?). A second advantage is that the map itself has value since the clones can be used for follow-up study. The disadvantage is that it is laborious and difficult to automate. It is also highly dependent on the nature of the subclones that are used. Early map-building efforts suffered from clones that were unstable at both ends of the size spectrum: yeast artificial chromosomes (YACs, 0.5–2 Mb) and cosmids (30 kb). Bacterial artificial chromosomes (BACs, ~150 kb), which are carried as single copy in *Escherichia coli*, have proven to stably clone most segments of the human genome, and the hierarchical shotgun strategy relied to a large extent on BACs for sequencing the human genome. Each BAC was then subcloned into small (~2 kb) fragments that were sequenced. Assembly of each BAC was followed by a second assembly step that joined all of the BAC sequences together on the basis of information from the map, thus the term "hierarchical" shotgun assembly. The BAC clones have also served as a distributed platform for finishing the human genome sequence to high quality, with different clones completed and checked at dozens of laboratories throughout the world (IHGSC, 2004).

2.2. Whole-genome shotgun

With the development of the Applied Biosystems 3700 Automated DNA Analyzer, the speed and accuracy with which raw DNA sequence data could be obtained increased dramatically. This forced a shift in thinking away from the map-based approaches toward a whole-genome shotgun strategy that would take maximum advantage of the increased output of raw sequence data. The whole-genome strategy relies on computational algorithms rather than extensive map-building to reassemble the genome sequence from the raw data (Weber and Myers, 1997). In the whole-genome shotgun strategy, the entire genome is sheared into small to medium fragments (~2 kb or ~10 kb); these are sequenced directly. By sequencing both ends of each subcloned fragment, the two sequences are constrained to be adjacent to one another in the genome; these clone end sequences are called mate pairs. A sufficient number of fragments are sequenced to represent the genome 5–10 times. This 5X to 10X coverage means that most DNA bases have been sequenced many

times, but a small fraction is missing because the coverage is random. The whole-genome strategy poses two problems: the shear number of fragments (about 30 million for 5X coverage of the human genome) and the presence of repetitive DNA. The first problem is largely computational – data management, data structures, and assembly algorithms have been developed to effectively organize and handle the quantity of data (Myers, *et al*., 2000, Batzoglou, *et al*., 2002). The second problem is more complicated and has implications for sequencing all eukaryotic genomes.

If the 2.9 billion base-pair sequence of the human genome were composed of a random distribution of the four DNA bases, any given sequence of at least 12 bases (4^{12}) would be highly likely to be unique in the genome. The 500 to 700 bases in a typical sequence fragment from an automated sequencer have more than enough information content to be unique in the human genome. The problem then is not the size of the genome but the presence of highly similar sequences at more than one location in the genome. There are several categories of these repeated sequences ranging from the ~300-bp Alu element (100 000 copies) to duplications of up to several megabases that are frequent around the centromeres of the chromosomes (*see* Article 26, **Segmental duplications and the human genome**, Volume 3). The length and identity of the repetitive elements determines the level of difficulty that they add to the assembly process. Repeats that are longer than the typical sequence read length and more similar than about 98.5% along their entire length are difficult to assign to their correct chromosomal location.

By obtaining mate-pair sequence from clones of several insert sizes, it is often possible to identify unique sequence that jumps across or spans repeats that are shorter than the average clone length. This approach can resolve the most common types of repetitive elements in the human genome. The mate pairs also serve to anchor together adjacent sequence contigs, resulting in long chains of correctly ordered sequence, with the gaps between contigs spanned by subclones. Additional computational techniques have been developed that attempt to improve on assembly in repeat-rich regions, especially relying on detection and classification of repeats, use of error-correction, and use of signature differences to separate repeat copies appropriately. Long tandem arrays of nearly identical repeats at the centromeres and telomeres of chromosomes cannot be sequenced with existing technology and approaches.

3. Prospects for the future

Sequencing of the human genome was a landmark event in the history of science. While a great deal was learned about the structure and content of the genome through an initial evaluation of the sequence, it has become increasingly clear that much more can be learned by comparing the genomes of multiple individuals and comparing the human genome to that of other primates, mammals, and other animals. The genomes of yeast, *C. elegans* (nematode worm), and *Drosophila melanogaster* (fruit fly) were obtained as part of the preparation for sequencing the human genome. Following human, the mouse, rat, and chimpanzee genomes have been completed to a "draft" stage. A "draft" genome sequence generally means that about 95% of the genome is covered in reasonably accurate sequence (less than

one error in 5000 bases) that is well ordered and mapped to chromosomes. Many additional eukaryotic genome-sequencing projects are either completed, underway, or planned (see Table 1).

Given what has been learned so far, what is the best strategy for sequencing additional large eukaryotic genomes? The choice of sequencing strategy for these organisms will depend on the goals of the sequencing project and on the answers to three primary questions: (1) How closely related is the genome to the genome of another organism that has been sequenced? (2) What is the nature of the repetitive elements in the genome? (3) Will the genome eventually be finished to very high quality? Each of these issues will be addressed in the following paragraphs.

3.1. Comparative sequencing

Increasingly, phylogenetic relatives are being sequenced to assist in the analysis and interpretation of a reference genome sequence (*see* Article 48, **Comparative sequencing of vertebrate genomes**, Volume 3). *Drosophila pseudoobscura*, *C. briggsae,* and chimpanzee were all selected for sequencing not only on their own merits but by what a comparison of their sequence might reveal about better-studied close relatives. In the case of chimpanzee, the nucleotide identity is so high that virtually every sequence read from the chimp genome can be assigned to a unique corresponding region of the human genome sequence, with the exception of sequences that are chimpanzee-specific. *Drosophila pseudoobscura* and *C. briggsae* are more distantly related to their respective references (*D. melanogaster* and *C. elegans*) – about the same phylogenetic distance apart as human and mouse. At this distance, most of the nonfunctional sequence is no longer conserved, facilitating identification of genes and conserved regulatory elements. The primary goal of these projects is to identify matching regions in a reference genome, and secondarily to identify the sequence unique to each genome, rather than to construct a high-quality finished sequence. In this case, a whole-genome shotgun strategy is clearly the most efficient way to generate high-quality draft sequence for comparison.

3.2. Repetitive elements

When long, nearly identical repeats are present, and when it is important to correctly resolve those repeat structures, such as for the study of chromosome evolution, a hierarchical or hybrid approach is likely to be the most effective. Whole-genome shotgun data can indicate the presence of repeated sequences (based on excess sequence coverage at those locations), but physically separating each copy of each repeat in BAC clones is the best way of correctly assembling each copy of long identical repeats. In repeat-rich genomes, construction of a BAC map by use of restriction fingerprint patterns can also be quite challenging, necessitating additional laboratory work to confirm both map and sequence.

3.3. Gap closure

Genome finishing – the process of filling gaps and confirming the quality of the entire sequence – is a quite different task from collecting the initial sequence data for a project, regardless of whether a hierarchical or whole-genome strategy is used. Plasmid subclones from each BAC or from whole-genome library used in the initial sequencing phase are selected for additional sequencing if they span a gap in a contig or a low-quality region. Additional finishing techniques involve sequencing of PCR-amplified segments of the genome and direct sequencing of BAC clones. One of the most difficult challenges of genome finishing is in closing gaps where no cloned DNA is present. These so-called physical gaps (because they are not physically present in any of the clone libraries) often result from portions of the genome that are not clonable in the standard cloning vectors that propagate in *E. coli*. For small genomes, a combination of sequencing subclones from whole-genome shotgun libraries, direct BAC or genomic sequencing, and PCR have been very successful at achieving high-quality genomic sequence. For larger metazoan genomes, where the whole-genome libraries contain millions of clones, finishing has primarily been performed on a BAC-by-BAC basis.

The cost per basepair for genome finishing is easily 50 times the cost of producing the first ∼95% of the sequence in draft form. The high cost and technical complexity of producing a finished genome sequence means that there will be many more draft than completely finished genome sequences for the foreseeable future. Methods such as comparative gene-finding programs (Parra *et al*., 2003; Flicek *et al*., 2003) that take best advantage of the incomplete information present in draft genome sequences continue to evolve.

4. Conclusion

As the cost of DNA sequencing continues to decline and analytical methods for assembling, annotating, and interpreting genome sequence improve, it is clear that more eukaryotic genomes will be sequenced. In fact, more than three dozen projects are already well along (Table 1) and many more are planned. The wealth of genome sequence data that will result will prove quite powerful for assisting in understanding the evolution of metazoan species, the structure of chromosomes, the sets of functional genes, and the sequences that control their expression.

Introductory Review

Genome sequencing of microbial species

Jacques Ravel and Claire M. Fraser
The Institute for Genomic Research, Rockville, MD, USA

1. Whole-genome shotgun cloning: a revolution in the microbial field

Microbes account for most of life on earth and are critical to its ecological balance. However, researchers have only scratched the surface of the tremendous biodiversity that these organisms display. Less than 1% has been cultured – only a minute proportion of the microbial diversity present in the environment. If this diversity is an indicator of the physiological, metabolic, and adaptation ability of the uncultured microorganisms, one can barely start to imagine the enormous diversity that can be discovered among the microbes on earth. No other field of research has embraced and applied genomic technology more than the field of microbiology, and genomic science has provided information that cannot be obtained by any other means. Microbial genomics has a broad range of applications, from understanding basic biological processes, host–pathogen interactions, and protein–protein interactions to discovering DNA variations that can be used in genotyping or forensic analyses. In addition, genomic data is being applied to unravel gene expression patterns through the development and analysis of DNA microarray data.

In 1995, The Institute for Genomic Research led by J. Craig Venter sparked a revolution in genomics by using whole-genome shotgun sequencing (Fleischmann *et al*., 1995) (Figure 1) to determine the first complete genome sequence of a free-living organism, the bacterium *Haemophilus influenzae*. Since that first report, more than 220 microbial genomes have been sequenced and at least another 650 are in progress (February 2005; **http://www.genomesonline.org/**) (Figure 2). This global effort has focused primarily on pathogens, which to date account for the majority of all genome projects (Figure 2), and has generated a large amount of raw material for in silico analysis. Additionally, in recent years, multiple in recent years, multiple strains of the same species, or multiple species of the same genus, have been the targets of sequencing projects, opening the possibility of comparing closely related genomes (*see* Article 61, **Comparative genomics of the ε-proteobacterial human pathogens *Helicobacter pylori* and *Campylobacter jejuni***, Volume 4). This will improve our understanding of microbial biology, pathogenicity, and evolution. However, the major challenge in the postgenomic era is to fully exploit and decipher this new accumulating wealth of information.

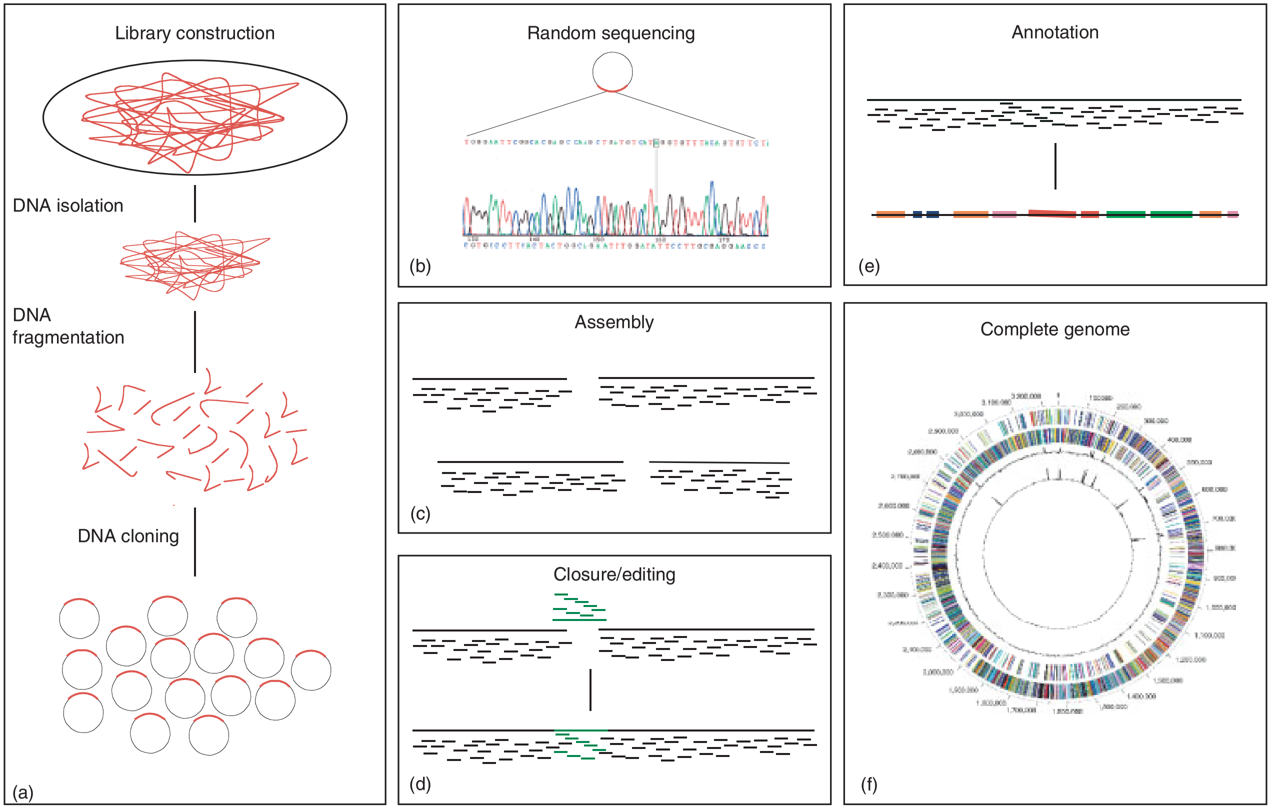

Figure 1 The steps involved in the whole-genome shotgun sequencing procedure. (a) Library construction. Total genomic DNA is extracted and mechanically sheared to smaller fragments. Each fragment is ligated into a cloning vector. (b) Random sequencing. About 6000 random clones per megabasepair are sequenced from both end of the insert to achieve 8X coverage. (c) The small sequences (~ 800 bp) are assembled into larger contigs using computational algorithms, such as the Celera Assembler. (d) The contigs are linked to each other during the closure phase, where the sequence is also manually edited. (e) Annotation. Using programs such as Glimmer, open reading frames (ORFs) are marked. The predicted protein sequences from these putative open reading frames are searched against nonredundant protein databases. (f) A Complete genome is obtained after manual curation of the annotation

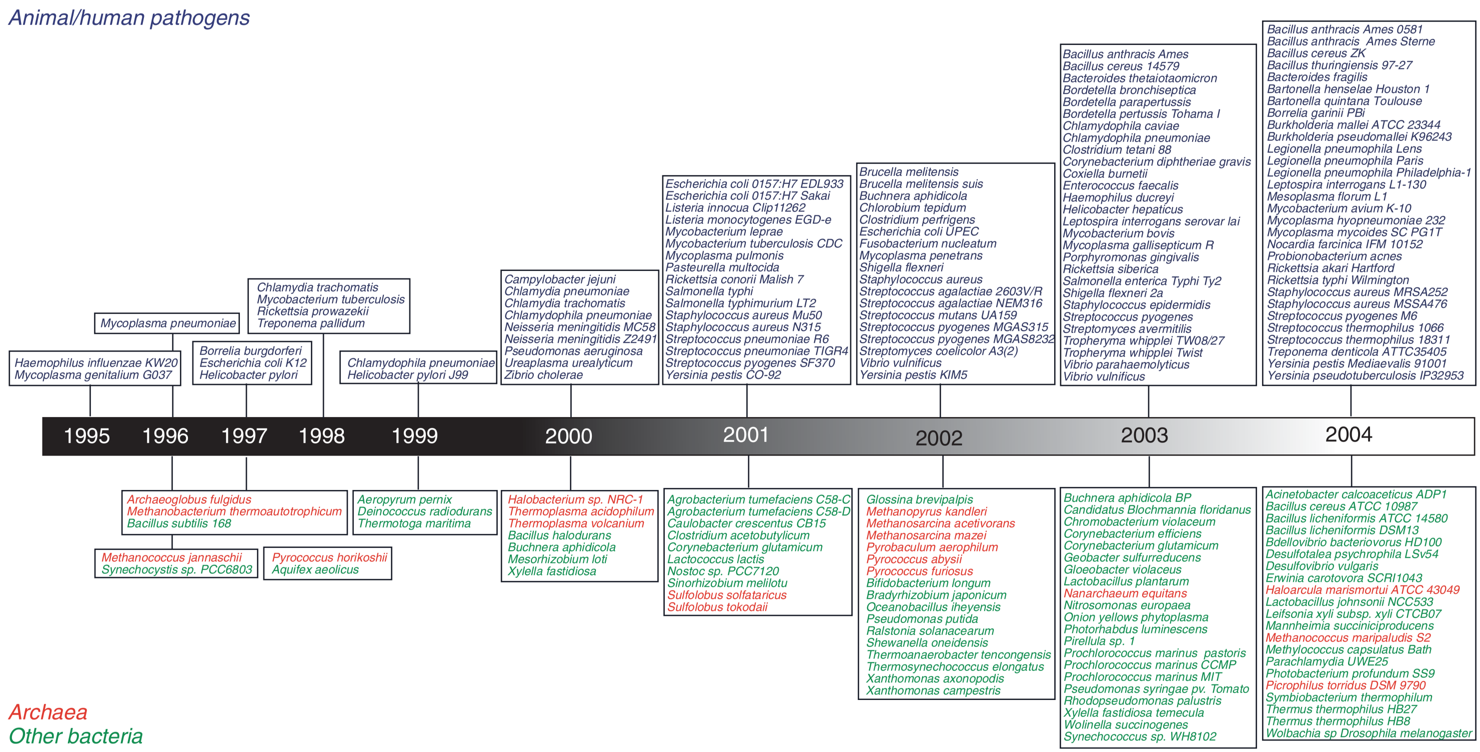

Figure 2 Completed genome sequencing project timeline

The whole-genome shotgun sequencing strategy does not require an initial mapping step to create a set of overlapping clones, and instead relies on computational methods (TIGR Assembler (Sutton *et al*., 1995), the Celera Assembler (Myers *et al*., 2000), and Phrap (**http://www.phrap.org**)) to correctly assemble tens of thousands of random DNA sequences 300–900-bp long. In some cases, the algorithms underlying the assembly software have also been shown to be powerful enough to successfully assemble larger eukaryotic genomes including the human genome (Venter *et al*., 2001; *see also* Article 25, **Genome assembly**, Volume 3). Given the current state of sequencing technologies, whole-genome shotgun sequencing remains the industry standard.

2. Genome annotation

The first step in the analysis of a completed and fully assembled genome is to determine the precise location and assign a putative function to all the protein coding regions, through a process known as annotation (*see* Article 29, ***In silico* approaches to functional analysis of proteins**, Volume 7). A wide variety of bioinformatics methods that have been developed to analyze sequence data have made annotation an increasingly sophisticated process. Computational gene finders (*see* Article 13, **Prokaryotic gene identification *in silico***, Volume 7) using Interpolated Markov modeling algorithms, such as Glimmer (Delcher *et al*., 1999), are routinely capable of finding more than 99% of all genes in a microbial genome. The predicted protein sequences from these putative open reading frames (ORFs) are searched against nonredundant protein databases and well-curated protein families, such as the PFAM (Bateman *et al*., 2002) and TIGRFAM (Haft *et al*., 2003) collections, that have been created using hidden Markov models (HMMs). HMMs are powerful statistical representations of groups of proteins that share sequence, and consequently, functional similarity. HMMs can represent very specific enzymatic functions or a superfamily of related functions. The use of HMMs has helped refine the annotation process. In addition, searches for PROSITE motifs (Sigrist *et al*., 2002), lipoproteins, signal peptides, and membrane-spanning regions are performed. On the basis of the evidence gathered, a two-stage annotation protocol is carried out whereby an initial automated annotation is followed by manual curation of each gene assignment by an expert biologist to ensure accuracy and consistency of the putative function of each predicted coding region. Proteins whose specific function cannot be confidently determined are designated "putative" or given a less specific family name. Proteins without any significant matches in any of the searches performed are annotated as hypothetical proteins. Consistent description and annotation of genes in different databases is critical to facilitate uniform queries across independent databases. This problem is being addressed by the development of controlled vocabularies (ontologies), such as the Gene Ontology (GO) project (The Gene Ontology Consortium, 2004; *see also* Article 82, **The Gene Ontology project**, Volume 8), where gene products are described in terms of their associated biological process, cellular components, and molecular functions in a species-independent manner.

3. What have we learned so far?

High-throughput genome sequencing technologies have only been around for less than 10 years, but the impact of these technologies has been profound. Genome sequence data have been obtained from representative species of all three domains of life (Figure 2); however, because of their relatively small size, bacterial and archaeal genomes have dominated the field (Figure 2). Taken together, comparative genome analysis has revealed interesting patterns pertaining to microbial species; for example, gene density in microbes is very consistent with about one gene per kilobase of DNA. Although we are able to identify microbial genes with a high degree of success, we cannot assign a function to about a quarter of all the ORFs in each species sequenced so far. This observation demonstrates how little is known about the biology and biochemistry of microbial species, and supports the idea of an incredible microbial diversity. These sets of genes that encode hypothetical proteins represent exciting opportunities for the research community and are not only potential sources of biological resources to be explored for future use, but also clearly indicate the need for further extensive genetic, enzymatic, and physiological analyses, before genomic data can be fully exploited.

Analysis of more than 150 microbial genome sequences has revealed an unexpected diversity and variability in genome size and structure, even in species previously thought to be identical. Many microbes possess diverse chromosome architectures that are quite different from the classical single circular chromosome. For example, the genome sequence of the human pathogen, *Vibrio cholerae*, unexpectedly revealed the presence of two circular chromosomes (Heidelberg *et al*., 2000), whereas the genome of *Borrelia burgdorferi* (Casjens *et al*., 2000; Fraser *et al*., 1997), the causative agent of Lyme disease, contained a relatively small (910 kb) linear chromosome and an unprecedented number of 21 linear and circular plasmids. On the other hand, the *Streptomyces coelicolor* linear chromosome is more than 9-Mb long (Bentley *et al*., 2002). In addition to differences in genome structure, microbial genomes vary largely in their GC content ranging from 24% to more than 70%. The effect of this disparity in GC content is reflected in the wide range of codon usage and the amino acid composition of proteins among various species.

As noted earlier, the study of bacterial pathogens has dominated and influenced the microbial genomic arena. This has resulted from the potential for developing a better understanding of virulence as well as identifying putative targets for vaccine and antimicrobial drugs. Access to the genomes of a variety of pathogens has allowed scientists to broaden their knowledge of pathogenicity through comparative genome analysis.

Organisms that belong to the same genus can differ in gene content by as much as 25% as it was found when the genome of *Escherichia coli* K-12 was compared to *E. coli* 0157:H7 (Hayashi *et al*., 2001; *see also* Article 51, **Genomics of enterobacteriaceae**, Volume 4). Insertion and deletion events appear to have played a major role and account for most of the differences observed. Pathogenicity islands, which are large blocks of self-mobile DNA that carry genes enabling an organism to act as a pathogen, have the ability to transfer from one organism and integrate into a new host. Other pathogens show little variation in chromosomal gene content, as demonstrated by the comparison of the genomes of two isolates of *Yersinia*

pestis (Deng *et al*., 2002; Parkhill *et al*., 2001), the etiologic agent of plague (*see* Article 58, ***Yersinia***, Volume 4). Remarkable differences in the chromosome structures, dominated by genome rearrangements, accounted for most of the variation observed between these two closely related strains. The differences appear to result from multiple inversions of genome segments at insertion sequences. *Y. pestis* sp. carry most of their virulence determinant on plasmids, which are absent in its ancestor, *Yersinia pseudotuberculosis*. A remarkable number of pseudogenes (degenerated and inactive genes) have been found on the genomes of *Y. pestis*, an indication of a recent and still evolving genome.

Often, differences between a pathogen and a nonpathogen cannot be explained solely by looking at gene presence or absence, but by subtle single nucleotide changes. These changes can have disproportionately large consequences. Important virulence genes have been shown to be completely inactivated by such changes. Virulence or survival can also be modulated by hypervariable short homopolymeric sequences, which vary in size during replication, and can result in frameshifts and inactivation or activation of important virulence genes, as seen in the human pathogens *Helicobacter pylori* and *Campylobacter jejuni* (Parkhill *et al*., 2000; *see also* Article 61, **Comparative genomics of the ε-proteobacterial human pathogens *Helicobacter pylori* and *Campylobacter jejuni***, Volume 4).

Genomic information can also be used to design novel vaccines and drugs (*see* Article 55, **Reverse vaccinology: a critical analysis**, Volume 4). In a pioneering study, Pizza *et al*. (2000) have exploited the genome sequence of *Neisseria meningitidis* to identify two highly conserved vaccine candidates within a set of cell-surface expressed or secreted proteins. There is no doubt that genomics has contributed enormously to a better understanding of bacterial pathogenicity, however, one genome is not enough. There is much that is still unknown and comparative genomics of close relatives of both pathogens and nonpathogens will be critical to unravel the secrets of microbial pathogenicity and continue the search for better and innovative vaccines or drugs.

The initial focus on pathogenic microbial species has shifted to include non-pathogenic environmental microbes. Understanding and accessing the tremendous microbial biochemical diversity that exists in the environment could have an important impact on industrial processes and help in resolving environmental issues, such as the bioremediation of human pollution.

Many archaea are considered extremophiles, as they often thrive under "extreme" conditions, such as high or low temperatures, high pressures or high salt concentrations among others. The novel enzymes encoded in these genomes (Figure 2) offer clear potential for biotechnological applications. In addition, genome analysis of the hyperthermophilic bacteria, *Thermotoga maritima* (Nelson *et al*., 1999) revealed that 20–25% of the genes in this species were more similar to genes from archaea than from bacteria, leading to a renewed interest in the process of lateral gene transfer and the role that it plays in microbial evolution and diversity (*see* Article 66, **Methods for detecting horizontal transfer of genes**, Volume 4).

Among the bacteria, the genome sequence of *Deinococcus radiodurans* (White *et al*., 1999), the most radiation-resistant organism on earth, and *Geobacter sulfurreducens* (Methe *et al*., 2003), which can clean up uranium and organic waste

contamination, will allow scientists to develop and optimize practical applications, such as the bioremediation of radioactive metals and harvesting electricity from waste organic matter. The genome of *Photorhabdus luminescens*, an insect pathogen living in symbiosis with a nematode has been fully sequenced (Duchaud *et al*., 2003). The analysis uncovered a variety of genes coding for entomopathogenic toxins, potentially useful in the fight against insect pests. Moreover, *P. luminescens* carries a large number of genes coding for the biosynthesis of antibiotics and fungicides, which could have potential applications for the treatment of infectious diseases. The genomes of *Streptomyces coelicolor* (Bentley *et al*., 2002) and *Streptomyces avermitilis* (Ikeda *et al*., 2003; Omura *et al*., 2001), both known to produce a wide variety of natural products, will assist in genome engineering to make novel and more efficient antimicrobial agents.

Researchers have only scratched the surface of microbial biodiversity. In order to harvest this enormous potential, genome shotgun sequencing is being applied to the environment. In a landmark study, the microbial populations from water samples collected in the Sargasso Sea were sequenced (Venter *et al*., 2004). An estimated 1.2 million new genes have been identified from at least 1800 genomic species. Similar techniques were applied to a community of microbes from a biofilm growing at pH 0.83 on the surface of acid mine drainage (Tyson *et al*., 2004). In this study, the low diversity genomic community was entirely reconstructed – the subsequent examination of the metabolic capabilities of this community gave valuable information on how each organism participates to the ecology of the biofilm. These types of microbial studies will help us define the entire repertoire of organisms in specialized niches and ultimately the mechanisms by which they interact in the biosphere.

With the technical advances of genome sequencing and analysis, genomics has also found an application in the field of microbial forensics. After the bioterror events of October 2001, where letters containing spores of *Bacillus anthracis*, the causative agent of anthrax, were sent through the mail, the genome of the *B. anthracis* isolate responsible for the death of a Florida man was rapidly sequenced and single nucleotide polymorphisms were found that could help identifying the origin of the samples used in this attack (Read *et al*., 2002).

4. Conclusions

Scientists in a number of different fields have employed the tools of genomics – no field has embraced and applied these technologies as quickly and effectively as the field of microbiology. Genomics will continue to improve the quality of human life well into the future as scientists continue to unravel the enormous amount of data that is being accumulated. More genome sequences are needed, new annotation tools must be developed and applied, and the databases that archive genomic data must be improved for better cross communication and up-to-date data. There is no question that genome-sequencing technologies are rapidly improving and that the data are going to accumulate at a faster pace in a future. The genomics community needs to be prepared to analyze and make use of this forthcoming deluge of

information. However, because genome sequence should not be considered an end-point and is only the first step in understanding biological processes, the microbial scientific community at large needs also to be trained and ready to make better use of this incredible resource.

Introductory Review

Hierarchical, ordered mapped large insert clone shotgun sequencing

Bruce A. Roe

University of Oklahoma, Norman, OK, USA

The underlying concept of employing dideoxynucleotides as chain terminators in the DNA sequencing reaction, to create a replicated nested fragment set that is size fractionated and detected, has changed little since it was first reported by Sanger *et al*. in 1970 (Sanger *et al*., 1977). In contrast, the detailed methods implemented in the laboratory to create, resolve, and detect the actual dideoxynucleotide sequence data have improved greatly owing to the discovery and use of improved DNA polymerases (Chien *et al*., 1976; Saiki *et al*., 1988), the development of automated electrophoresis instrumentation (Ansorge and Barker, 1984; Smith *et al*., 1986; Karger *et al*., 1991), and the availability of highly sensitive fluorescently labeled nucleic acid derivatives that can be automatically detected efficiently after laser excitation (Bauer, 1990). Although all of these methodological improvements were important, it was the introduction of commercially available automated DNA sequencing instruments, and a significant influx of massive public and private sector funding (Choudhuri, 2003) over the last decade, that paved the way for the yearly almost log-scale increases in the amount of DNA sequenced data collected and a parallel significant reduction in DNA sequencing cost. As a result, a paradigm shift evolved that increased the emphasis on approaches and methods to generate and assemble large target DNA sequences, rather than the actual DNA sequencing data collection process. Clearly, the latter still remains important as improvements continue to be made through the introduction of newer DNA sequencing instruments, several of which are described in this section, as well as significant improvements in DNA sequence assembly programs, as described in other chapters. However, as with almost all science, changes evolve slowly over time. This was the case for DNA sequencing, which began by directed sequencing of restriction digested and subcloned short target sequences and that subsequently evolved into a hierarchical map-based approach to sequence larger genomic regions and then into the shotgun sequencing the underlying minimal tiling path ordered large insert clones combined with more directed closure and finishing phases. These methods now have evolved into widespread implementation of whole-genome shotgun sequencing and assembly to order and orient contiguous

but gapped sequences without much attention to the closure and finishing of the entire genome.

Initially, as the DNA sequencing data collection technologies evolved over the past decade, several groups also focused on developing strategies for obtaining the target DNA that subsequently was subjected to the sequencing process. Here the genomic DNA either was cleaved by enzymatic or physical methods and shotgun libraries were produced using various host/vector systems. Cosmid and yeast artificial chromosome (YAC) vectors (McCormick *et al*., 1987; Burke and Olson, 1991) initially were employed for this purpose, and hybridization methods were used to determine which cosmid or YAC clone(s) encoded the target region of interest (Feinberg and Vogelstein, 1983). When multiple, adjacent probes were used, either created as PCR products amplified off end-sequenced or fully sequenced cosmids (termed over-goes) or from sequencing fragmented YACs, it also was possible to overlap the cosmids and/or YACs and to generate a tiling path covering regions of genomic DNA several orders of magnitude larger than that covered by the initial cosmid or YAC. Although a valuable approach, using these hybridization approaches to completely sequence a large genomic region through making a tiling path of a large number of target clones was both time consuming and often prone to errors that could be traced to the specificity of the hybridization probe used. In addition, both YAC and cosmid vector systems had the tendency to either lose portions of the inserted DNA or otherwise rearrange it since there was little selective pressure to accurately maintain the originally cloned genomic DNA fragment. Therefore, more stable host/vector systems were developed including, namely, bacterial artificial chromosome (BAC)-based clones that could contain between 100 000 and 200 000 bp of genomic DNA insert (Shizuya *et al*., 1992) and fosmid-based cloning vectors that typically contained ∼40 000 bp of inserted genomic DNA (Kim *et al*., 1992). Since both types of clone libraries were engineered so that they were much less prone to deletions or rearrangements, improved methods to generate tiling paths for large segments of genomic DNA were now possible.

Thus, the hierarchical map-based approach needed to complete the sequence of large reference genomes, for example, flies, worms, humans, and mice, necessitated the development of BAC fingerprinting methods to create a tiling path of overlapping individual clones that then could be used to generate a minimal smaller set of BAC clones for eventual sequencing. Initially, these physical maps were constructed using high-throughput polyacrylamide gel electrophoresis to separate the restriction enzyme–digested BAC clone DNA followed by visualization using a fluorimager, followed by normalizing the band values and gel traces by editing the digitized images (Sulston *et al*., 1989). More recently, capillary electrophoresis of fluorescent-labeled DNA restriction digests has resulted in a more automated process by which thousands of BACs from a library can be rapidly fingerprinted (Ding *et al*., 1999; Ding *et al*., 2001). In either case, the resulting visualized and normalized restriction digestion patterns then are compared and overlapped via computer-based methods such as FPC (Marra *et al*., 1997) in which the clones are ordered into tiling paths on the basis of the occurrence of shared bands.

Once a minimum tiling path is obtained, the DNA from the underlying BAC clones is isolated and subjected to shotgun sequencing. This process entails breaking a large target DNA randomly into smaller fragments that then are cloned

into a vector. Initially, m13 phage vectors (Messing *et al*., 1977) were used for this purpose, but today double-stranded pUC-based plasmid vectors (Vieira and Messing, 1982) are used almost exclusively as both ends of the cloned insert can be more easily sequenced from the plasmid than from the single-stranded phage vector. After end sequencing, overlapping identical sequences are assembled to recreate the sequence of the original sequence of the BAC-cloned insert. This process is analogous to reconstituting the front page of a daily newspaper by putting thousands of copies of it through a shredder and then overlaying the pieces with similar words and pictures to give a single copy of the initial page.

The initial description of shotgun cloning was given by Steve Anderson in 1981, when he described the cloning of the products of a partial DNAse 1 digestion of a 4257-bp target fragment of the bovine mitochondrial genome into M13 vectors (Anderson, 1981) followed by randomly picking subclones and obtaining the end sequences of each of them. The resulting overlapping sequences then could be assembled into a final, contiguous, consensus sequence representing that of the initial DNA target fragment. This shotgun technique took several years to become widely accepted because the high number of DNA sequencing reactions and subsequent polyacrylamide gel–generated sequences that had to be manually read were both too expensive and too highly labor intensive. It was not until almost a decade later that two independent laboratories, Lee Hood's group at Cal Tech (Smith *et al*., 1986) and Ansorge's group at the EMBL laboratory in Heidelberg, Germany (Voss *et al*., 1990), introduced automated DNA sequence data collection methods that resulted in the first commercially available fluorescent-based DNA sequencers that were produced by Applied Biosystems and Pharmacia, respectively, in the early 1990s. The major advantage of these fluorescent-based DNA sequencing instruments was that the data collection process was automated. However, since the fluorescent-labeled reactions produced weaker fluorescent signal than the radioactive-labeled reactions, they required higher amounts of single-stranded DNA templates and fluorescent-labeled primers to produce the required signal strength during a constant temperature incubation. The later introduction of thermostable DNA polymerases allowing reaction temperature cycling, termed "cycle sequencing" (Murray, 1989), and fluorescent-labeled dideoxynucleotide terminators, eventually made it possible to use much less DNA template in a single reaction. This, when coupled with the automated data collection on slab gel–equipped instruments, ensured that the shotgun sequencing approach truly became widely accepted. More recently, the introduction of capillary-based DNA sequence data collection instruments, by Applied Biosystems, Molecular Dynamics, and Beckman, that have shorter runtimes and automated sample loading than previous slab gel–based machines, resulted in the elimination of the labor-intensive sequencing reaction pipetting and data collection steps.

This chapter includes descriptions of the work of several groups that have resulted in sequencing large numbers of DNAs from both higher eukaryotes (*see* Article 1, **Eukaryotic genomics**, Volume 3) and microbial genomes (*see* Article 2, **Genome sequencing of microbial species**, Volume 3), as well as a discussion of sequencing template preparation methods (*see* Article 4, **Sequencing templates – shotgun clone isolation versus amplification approaches**, Volume 3) and a description of robotics and automation techniques (*see* Article 5, **Robotics and**

automation, Volume 3). These articles are followed by contributions from three of the leading groups in developing the next generation of high throughput DNA sequencing methods that include microelectrophoresis devices for DNA sequencing (*see* Article 6, **Microelectrophoresis devices for DNA sequencing**, Volume 3), single molecule array-based sequencing (*see* Article 7, **Single molecule array-based sequencing**, Volume 3), and real-time DNA sequencing (*see* Article 8, **Real-time DNA sequencing**, Volume 3).

Sequencing templates – shotgun clone isolation versus amplification approaches

Rebecca Deadman and Carl W. Fuller
GE Healthcare, Piscataway, NJ, USA

1. Introduction

High-quality DNA is essential to obtaining the greatest success in DNA sequencing. Sequencing quality DNA should contain the lowest possible level of contaminating host DNA, have consistent yields from sample to sample, and be in sufficient quantities to perform multiple sequence reactions. Many thousands of clones are required whether a whole-genome shotgun or clone-by-clone approach is taken so the DNA isolation method must be amenable to automation for a high-throughput sequencing process.

To produce sequencing templates, random fragments of DNA are inserted into cloning vectors and propagated in *Escherichia coli*. Individual clones are cultured in 0.5–2 ml volumes and the episome containing the clone DNA is extracted and purified. Each method differs in the quality of DNA produced, the length of time and cost to perform, and its suitability to automation. Variable DNA concentrations from sample to sample make it difficult to optimize sequencing reactions. DNA isolation may be one of the most basic and routine molecular biology techniques but it is one of the most important for success.

Traditional extraction methods involve chemical isolation of the subclone DNA, taking advantage of the mass difference between the plasmid and chromosomal DNA. Some techniques further involve immobilization of the plasmid to a solid structure. DNA amplification methods circumvent the cell growth step, allowing DNA isolation to proceed directly from bacterial colonies or glycerol stocks. Table 1 shows a comparison of three common methods of DNA preparation for plasmid clones – alkaline lysis (Birnboim and Doly, 1979), solid-phase reversible immobilization (SPRI) (Hawkins *et al*., 1994), and rolling circle amplification (RCA) (Dean *et al*., 2001).

2. Cloning and sequencing vectors

Bacterial artificial chromosomes (BACs) are probably the most common clone type used today for genomic library construction. Libraries in BAC vectors such as

Table 1 Comparison of some popular DNA preparation methods

	DNA isolation method		
	Alkaline lysis	SPRI	RCA
Time to prepare 96 templates	18 h, including overnight culture.	16.5 h, including overnight culture.	4.5 h
Yield	7 µg from 1.5-ml culture	4 µg from 1.5-ml culture	1.5 µg from single colony
Quality of DNA	Good	High	High
Sample-to-sample variability	High	Low	No variability
Number of liquid-handling steps	8	7	2
Plastic ware	Culture plate Microwell plate	Culture plate Microwell plate	Microwell plate
Equipment required	Incubator Centrifuge Vortex	Incubator Magnet	Water bath
Ease of automation	Not easily automated	Easily automated	Easily automated
Key reagents	Bacterial growth media GTE NaOH SDS KOAc Ethanol	Bacterial growth media SprintPrep buffer Isopropanol Ethanol	Denature buffer TempliPhi Premix

pBACe3.6 were used for many of the model organism sequencing projects including human and mouse (Osoegawa *et al*., 2000). The BAC cloning vectors are based on the naturally occurring F-factor found in *E. coli* and they are maintained as supercoiled circular episomes within the bacteria, usually with a single copy per cell. The vector to insert ratio for BACs is very good. Inserts up to 300 kilobases (kb) can be stably introduced into the approximately 8-kb vector. Fosmid vectors (Kim *et al*., 1992) also contain the *E. coli* F-factor, but only 40 kb can be stably maintained in these vectors.

The most common sequencing vectors by far are the double-stranded plasmids, usually the high copy number pUC-based plasmids (Yanisch-Perron *et al*., 1985). With double-stranded vectors, sequence data from both forward and reverse strands can aid assembly of the genome or clone in question (Roach *et al*., 1995). The previously favored single-stranded bacteriophage M13-based vectors are now usually used only for regions that are not stably maintained in pUC plasmids (Chissoe *et al*., 1997). Increased sequence readlength from improvements in sequencing chemistry and instrumentation has allowed an increase in the typical subclone insert size. Sequence readlengths of 700–800 base pairs (bp) are not uncommon and so an average insert size of 2–4 kb is now routinely used for shotgun libraries in plasmid vectors.

3. Traditional plasmid DNA isolation techniques

When Wilson *et al*. (1992) described the methods involved in sequencing a 95-kb section of the mouse genome, the processing of 24 M13-based subclones took one

individual almost a day. With current levels of automation, thousands of subclones can be prepared per day, with human involvement reduced to loading and unloading of microwell plates and reagents.

The most common method for extraction of plasmid DNA from *E. coli* cells is still alkaline lysis. This method takes advantage of the mass differences between plasmid and chromosomal DNA. Bacteria are lysed by treatment with a solution containing sodium dodecyl sulfate (SDS) (CAS # 151-21-3) that denatures the proteins, and sodium hydroxide (NaOH) (CAS # 1310-73-2) that denatures chromosomal DNA. The mixture is neutralized with potassium acetate (KOAc) (CAS # 127-08-2) and the supercoiled, plasmid DNA reanneals rapidly due to its secondary structure and smaller size. The chromosomal DNA and proteins form a solid precipitate with the insoluble potassium salt and SDS and pellet under centrifugation. The plasmid is further purified from the supernatant by alcohol precipitation and washing.

An alternative method to alkaline lysis is the boiling miniprep (Holmes and Quigley, 1981). The cells are lysed by treatment with lysozyme (CAS # 12650-88-3) and heating in the presence of Triton X-100 (CAS # 9002-93-1) and sucrose (CAS # 57-50-1). This procedure releases the plasmid DNA but not the chromosomal DNA from the cell. Centrifugation pellets the cell debris including most of the chromosomal DNA, leaving the plasmid DNA in the supernatant, which is further purified by alcohol precipitation. This method is quicker than alkaline lysis, but the quality of the DNA is lower, having higher chromosomal DNA contamination and more variable yield.

Variability in yield can have a dramatic effect on sequence DNA quality. It is difficult to optimize sequencing reactions when the DNA templates vary widely in concentration. In addition, capillaries in DNA analysis systems can be adversely affected by excessive amounts of DNA in the samples. Sequencing capillaries vary in the range of DNA that they can tolerate, and the type of sequencing instrument should be a consideration when deciding which isolation method to use.

One of the main advantages of both the alkaline lysis and boiling methods is cost. The reagents are inexpensive and easily obtainable and no special equipment is needed, beyond a centrifuge. Once the overnight cell growth is complete, the procedures are fairly quick; two 96-well plates of cultures can be processed in a few hours by a single technician. DNA quality is usable, but probably the lowest of the methods that will be discussed – a chromosomal DNA contamination level of 5–10 % can be expected. As these methods involve centrifugation, they are difficult to automate which is vital for either a cost effective or high-throughput operation.

4. Filter-based purification methods

Most of the commercially available plasmid purification products, such as R.E.A.L™ (rapid extraction alkaline lysis) Prep 96 Plasmid Kit (Qiagen Inc.), begin with the alkaline lysis procedure but differ in the purification step. Following cell resuspension, lysis, and neutralization, the lysate is passed through a membrane that binds the plasmid DNA. The plasmid DNA is washed and then eluted with

water or Tris-EDTA (TE) buffer (CAS # 77-86-1 and 139-33-3). These so-called bind-wash-elute products usually use glass fiber membranes or glass beads that bind DNA in the presence of a chaotropic salt such as guanidine hydrochloride (CAS # 50-01-1). The lysate is usually drawn through the membrane using a vacuum manifold.

These methods eliminate some of the centrifugation steps in the alkaline lysis protocol, making them more amenable to automation and are available in single, 96-well and 384-well formats. Without the alcohol precipitation step, the methods are generally quicker than standard alkaline lysis methods. A 96-well plate of minipreps can be prepared from grown cultures in 45 min. DNA purity with these products is usually higher than with the standard alkaline lysis procedure but the overall cost is also increased owing to the additional filter plates required.

5. Alternative plasmid purification methods

5.1. *Solid phase reverse immobilization (SPRI)*

Technologies that use physical isolation of DNA instead of chemical isolation are commercially available. One such method, SPRI, is used in the SprintPrep™ and CosMCPrep™ DNA purification kits (Agencourt Biosciences Corp.). Carboxyl-coated magnetic beads in the presence of high polyethylene glycol (PEG), alcohol, and salts bind plasmid DNA from lysed bacterial cultures (Figure 1). Cell pelleting and resuspension steps are eliminated by using magnetic separation. Beads with absorbed DNA are washed with ethanol (CAS # 64-17-5) to remove contaminants, then the plasmid DNA is eluted from the beads with water. As this method requires neither centrifuge nor vacuum manifold, it can easily be automated. This method is the quickest of the ones discussed here. A 96-well plate of bacterial cultures can be processed in about 20 min.

5.2. *Rolling circle amplification*

All of the methods discussed so far employ overnight cell growth to propagate plasmid-containing cells and thus amplify the cloned DNA. These methods are effective when high copy-number vectors are used. An alternative strategy is to use multiply primed RCA. This method uses a highly processive, strand-displacing DNA polymerase to amplify the plasmid DNA directly from bacterial colonies, eliminating the need for overnight culture. TempliPhi™ DNA Sequencing Template Amplification kits (GE Healthcare) exploit this technology. Over 10 000-fold amplification can be achieved in as little as 4 h using random hexamer primers that initiate multiple replication forks (Figure 2).

The key to the technology is the DNA polymerase from bacteriophage Phi29. This DNA polymerase is highly processive, incorporating more than 70 000 nucleotides in a single binding event (Blanco *et al*., 1989). RCA is an isothermal reaction and does not require cycling to denature the DNA strands for the next round of amplification as in polymerase chain reaction (PCR). When the enzyme

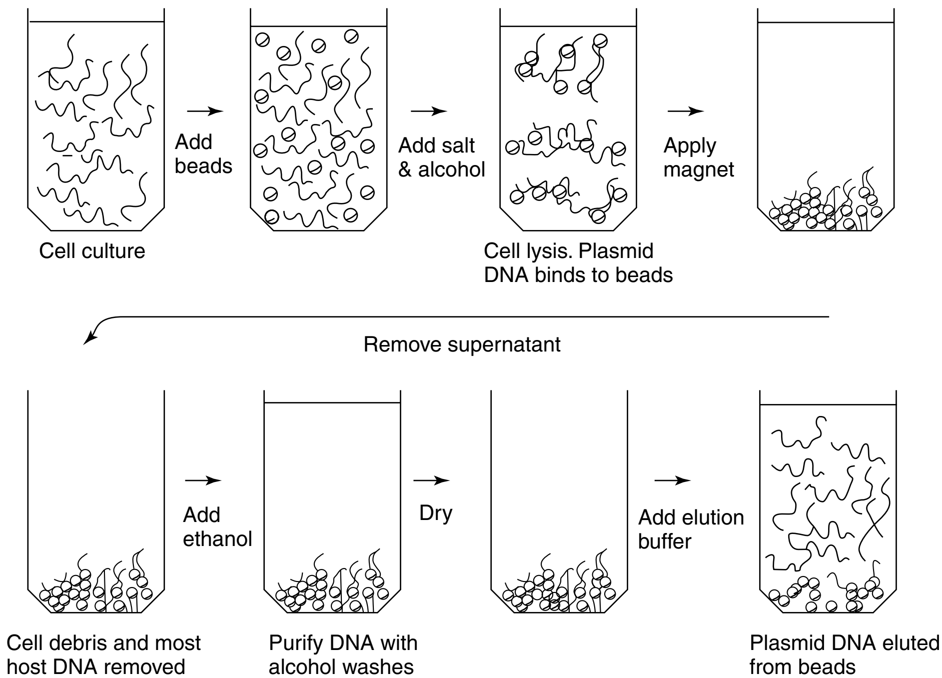

Figure 1 Schematic of SPRI plasmid isolation procedure. Paramagnetic beads are added to bacterial culture. Cells are lysed, and plasmid DNA binds to paramagnetic beads in the presence of isopropanol and salts. Immobilized plasmid DNA is further purified by ethanol washes. DNA is eluted from the beads with water

encounters a nontemplate strand, it simply displaces it, generating single-stranded DNA available for further primer annealing. This leads to exponential amplification of both strands. Phi29 DNA polymerase has a $3'-5'$ exonuclease activity, giving it an error rate of only 1 in 10^6-10^7 (Esteban *et al*., 1993), approximately 100 times lower than *Taq* DNA polymerase (Dunning *et al*., 1988). The product of the RCA process is double-stranded concatamers of the input DNA sequence (Figure 3). Approximately 80% of the product can be digested with restriction endonucleases generating unit-length DNA fragments (Dean *et al*., 2001).

There are a number of advantages to this technique. Speed is an obvious one; sequence ready DNA can be prepared in under 5 h, directly from colonies, with only 20 min of hands-on time for a 384-well plate of templates. Another is consistency of yield. Properly formulated, RCA is an exponential reaction, terminating only when all the nucleotides in the reaction mixture have been exhausted. Every reaction yields the same mass of DNA product, making optimization of downstream sequencing processes much simpler and more reliable than with other methods. In addition, the amplification product can be used directly in sequencing reactions without any further purification. It is not necessary to remove the excess hexamers prior to sequencing as they will not participate in the sequencing reaction owing to their lower melting temperature compared to sequencing primers. The one major disadvantage may be cost, the reagents being more expensive than those used in the alkaline lysis procedure but on par with other commercial plasmid purification

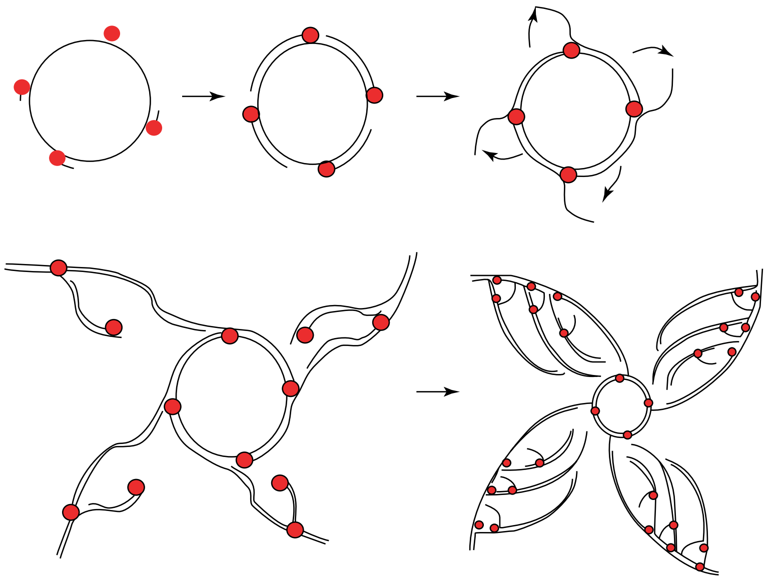

Figure 2 Schematic of rolling circle amplification. Random hexamers bind to the circular template, generating multiple replication forks. Phi29 DNA polymerase displaces the nontemplate strand, making them available for further primer binding. The amplification product is double-stranded tandem copies of the starting circle

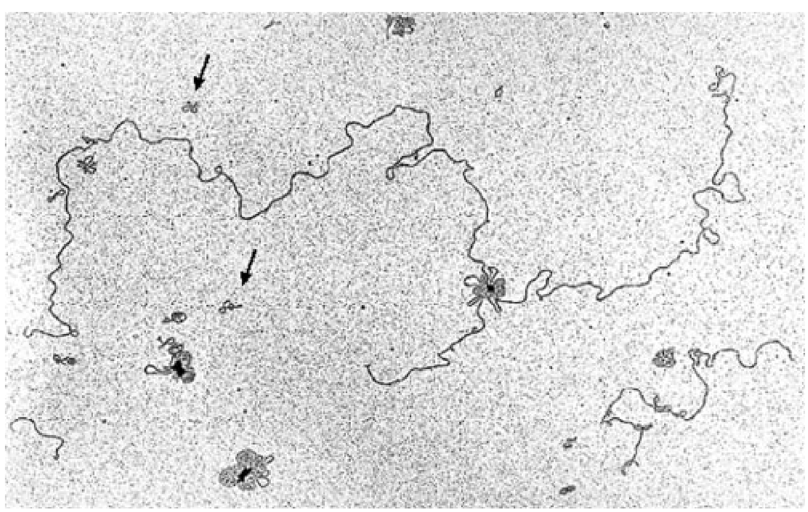

Figure 3 Electromicrograph of plasmid DNA amplified by rolling circle amplification. Image shows RCA products after 5 min amplification. Arrows indicate unit-length (nonamplified) plasmid molecules

methods. The increase in reagent cost may be offset by savings in the time, labor, and space, which can be achieved by the elimination of the bacterial growth and many liquid handling steps.

5.3. Colony PCR

Another method that bypasses culture growth is colony PCR (Gussow *et al.*, 1989). A colony is simply picked into a PCR cocktail containing primers in the flanking vector sequence designed to specifically amplify the entire insert. It is often necessary to purify the PCR product from the primers and excess nucleotides to prevent them from interfering in the sequencing reaction. Kits such as ExoSAP-IT™ (usb Corp.) contain *E. coli* exonuclease I and shrimp alkaline phosphatase to remove the single-stranded primers and free nucleotides. Colony PCR is a quick and simple method but has not been extensively used because of the amplification errors that can be introduced by the PCR process. The guidelines set out by the major sequencing centers on finishing DNA sequence (G16 Finishing Standards for the Human Genome Project – Version September 7, 2001 **http://www.genome.wustl.edu/Overview/finrulesname.php?G16=1**) limit the amount of the genome that can have sequence coverage only from PCR products, and any sequence derived from PCR products must be annotated. Despite the error rate, this method can be useful for quick colony screening.

6. Factors affecting plasmid yield

Plasmid yield is dependent on many factors including type of plasmid, (high or low copy number), size of plasmid, and *E. coli* host strain. For instance, copy number can vary from approximately 1000 for pUC vectors down to less than 10 for vectors with functional copy-control. Plasmid size should be taken into account when choosing an isolation procedure. Methods such as the boiling miniprep that rely on plasmid DNA being released from the cell when lysed are not suitable for large insert plasmids (>10 kb) as the plasmids get withheld along with the chromosomal DNA. This should also be a consideration for RCA where the harsher lysis conditions required to release the plasmid may release host DNA, which will be amplified in addition to the plasmid DNA. This is especially true for large vectors such as fosmids (see below). Optimization of PCR conditions may be required for colony PCR of plasmids with inserts larger than about 2 kb. Different PCR conditions may be required for vectors with different sized insert.

For alkaline lysis–based methods, including the filter-based methods, ideal yield from a 1.3-ml culture of a high-copy plasmid such as pUC is approximately 7 μg, although there is considerable sample to sample variability. With RCA, the yield is dependent on the amount of nucleotide in the reaction. Currently, two DNA amplification kits are available commercially from GE Healthcare that produce either 1.5 μg in about 4 h or 3.5 μg in 18 h. These reactions can be scaled up or down if more or less DNA is needed. With the SprintPrep DNA purification kit from Agencourt Biosciences, 150 μl of culture yields about 400 ng of plasmid DNA.

7. Preparation of M13-based vector DNA

Purification of M13-vectors is much simpler than for plasmids because the M13 phage particles are released into the growth media. Cells are pelleted by centrifugation, and the phage particles precipitated from the supernatant using PEG (CAS # 25322-68-3) and salt. The M13 DNA is released from the coat protein during the denaturation steps of cycle sequencing so no further purification is necessary for sequencing quality M13 DNA. If ultra pure M13 DNA is required, the DNA can be further purified by alcohol precipitation and washing. RCA and PCR can be used to amplify M13 templates directly from plaques. The product of both methods is double stranded and can immediately be sequenced from both the forward and reverse strands.

8. Preparation of fosmid and BAC DNA

The difficulty with purification of large vector constructs is twofold. First, they are usually present in only one or two copies per cell (although high copy-number vectors are recently available) and second, they are much larger than subclones, making purification based on size more difficult. There are many different protocols available for the isolation of BAC DNA, depending on the purity of DNA required. For sequencing purposes, some chromosomal DNA contamination is acceptable, but if the same DNA is to be used for fingerprinting, then a method that gives higher purity DNA may be required.

Alkaline lysis is used to purify BACs and fosmids as they are maintained in *E. coli* as supercoiled episomes. Owing to the increased size of BAC and fosmid constructs compared to plasmid subclones, some BAC DNA inevitably complexes with the SDS, protein, and chromosomal DNA, resulting in low yields. Some protocols allow the samples to stand for 30 min after the addition of the potassium acetate, presumably to allow time for the large construct DNA to reanneal. Depending on the level of purity required, either alcohol precipitation or cesium chloride gradient centrifugation can be performed following neutralization to improve DNA quality.

Filter-based methods are also available for purification of large constructs. As for plasmid purification kits, they are based on the alkaline lysis method followed by membrane purification in place of alcohol precipitation. Many employ the same glass fiber membranes used for plasmid isolation, while others such as the Montage BAC_{96} Miniprep Kit (Millipore) use size exclusion membranes. A 96-well plate of cultures can be processed in approximately 60 min with these vacuum or centrifuge-based filtration systems. Typical yields range from 0.5 to 1 μg from a 1-ml culture.

RCA can be used to amplify large constructs giving a much higher yield of DNA than alkaline lysis–based methods. Approximately 5 μg of DNA can be obtained with TempliPhi Large Construct DNA Amplification kit (GE Healthcare) in 18 h from 1 ng of starting DNA. Random hexamers in the kit will amplify any DNA in the reaction so that higher levels of chromosomal DNA are often present in the amplification product if purified BAC DNA is not used as the starting material. As a result, and because of the large size of BAC clones, a higher concentration

of DNA may have to be used in the sequencing reaction, and the RCA product is not ideal for library construction. The advantage of the method is that virtually any form of DNA can be the starting material, such as glycerol stocks or colonies, eliminating the need for culture growth.

9. Summary

The quality of sequencing template DNA directly affects the quality of sequence data obtainable. There are many template preparation methods available but no single method is perfect for all choices of vector, host strain, and sequencing application. Alkaline lysis remains the most popular method for isolating plasmid DNA but this and other inexpensive methods tend to be more time consuming, are difficult to automate, and suffer from low and variable yields. Consistent yield is the main concern when sequencing large numbers of templates, or when using a wide variety of vectors or hosts. It is difficult to establish a high-throughput sequencing pipeline when template yields are inconsistent. The column- or filter-based DNA purification methods offer higher yields and a higher purity product but still require many time-consuming steps and are subject to the same sample variability issues. These products are more expensive than simple miniprep methods. The SPRI technology eliminates many of the laborious steps of the traditional methods and as such is one of the quickest DNA purification methods available. Amplification technologies currently offer the most consistent yield and greatest flexibility for sequencing template preparation. RCA may be the method of choice when reliability, despite variation in vector and host strain, is of paramount importance. The RCA method eliminates culturing and purification steps, which can make it an attractive alternative despite higher initial costs. As DNA quality, quantity, and consistency vary between methods and with differences in host strain and vector, the choice of method has to be carefully considered, and more than one method may be required to meet all the sequencing template preparation needs.

Specialist Review

Robotics and automation

Elaine R. Mardis
Washington University School of Medicine, St. Louis, MO, USA

1. Introductory remarks

Reflecting on the past 15 years of the history of large-scale DNA sequencing, it is incredible to realize just how far this discipline has progressed in a relatively short period of time. The efforts, hopes, fears, and failures of many molecular biologists, engineers, and others have been played out in the arena of academic and industrial labs – all pursuing the advancement of the field. Nowhere have their efforts been more critical to these achievements than in the incorporation of robotics and automation to render tasks once entrusted to skilled technicians into the routine, programmed movements of robotic systems. This overview aims to trace the early origins of those efforts and their metamorphosis over time, as well as to present a state-of-the-art picture of high-throughput DNA sequence production for the interested reader.

2. Overview: critical components that rendered DNA sequence an "automatable" process

Before one can begin to chart the history of robotics and automation in large-scale DNA sequencing efforts, however, it is important to point out many of the factors that played a role in rendering DNA sequencing an "automatable" process. First and foremost, sequencing developed, over time, into a routine process that utilized the same series of steps and the same components at each iteration. One enormous contributor to the routine nature of sequencing reactions was encompassed by the development of cycled sequencing – an offshoot of PCR, in which a single primer is extended by a thermostable DNA polymerase on a template in the presence of dNTPs and ddNTPs, producing a great excess of dideoxy terminated fragments (in comparison to the input template amount) and eliminating stepwise addition of DNA sequencing reagents as in the past (McBride *et al*., 1989; Craxton, 1993). Later, a series of substantial improvements to DNA sequencing methods (enzymology and DNA fragment labeling in particular) and to associated methods such as DNA template preparation further enhanced the ability to automate reaction assembly by robotic means. Several of these key developments are highlighted below. Another important contribution to the routine nature of DNA sequencing

was that the detection hardware, DNA sequencing instruments, also improved significantly over time. A third development was the adaptation, borrowed from the clinical laboratory, of the multiwell microtiter plate format for sample handling, which provided a reproducible footprint and well-to-well spacing for access and plate handling by robotic devices. Along the way, industrial practices such as bulk solution manufacturing and quality control were developed and implemented by many high-throughput DNA sequencing facilities, contributing a reliability factor to the reagents used in these processes. The combination of these factors, along with the ever-increasing scale of DNA sequencing throughput became such that only robotic solutions were appropriate, especially in their elimination of manual errors, their ease of sample tracking (via bar code reading/entry), and the reproducible nature of their product.

3. Early days – the "do-it-yourself" era

When we and others first started thinking about automating DNA sequencing and its associated processes in mid-1980, suffice it to say that there were very few instrument manufacturers thinking about the same things. This situation improved slowly over time, but many first efforts at "automation" were fairly rudimentary, not truly "automated", and nearly always enlisted devices that were borrowed from other disciplines or were devised by genome center–associated engineering teams responding to demands for increased throughput. Predominantly, early efforts were aimed at applying robotics to individual processes in the DNA sequencing workflow rather than at the development of larger, integrated systems.

One of the first areas to be pinpointed for robotics application was that of liquid transfer, since reliable, reproducible manual liquid transfer of microliter volumes is a function of the quality of the pipettor and the skill of the person using it (not to mention adjunct factors of fatigue and interruption!). Most commercially available liquid-handling robots were designed for clinical applications that utilized the multiwell microtiter plate format. Hence, the adaptation of 96 well microtiter plates into DNA sequencing methods likely was a happenstance of the need for robotic liquid handling. Although many of the robots were standalone devices, they brought a reliability and reproducibility aspect to the sequencing process and enhanced throughput at very early stages. For example, our Center used the Robbins Hydra96™ pipettors to both prepare DNA templates (Mardis, 1994) and to pipette sequencing reactions for many years, and very early reports of sequencing reaction and DNA isolation methods used the Beckman Biomek 1000 robot (Wilson *et al*., 1988; Mardis and Roe, 1989; Koop *et al*., 1990).

Upstream of the DNA isolation and sequencing processes, harvesting recombinant clones from agar plates was another process that was targeted early on for automation, for quite obvious reasons – the process initially was done by technicians whose tools consisted of lightboxes (for imaging the plaques or colonies) and beakers of sterile wooden toothpicks (for harvesting the plaques or colonies). Several robots were designed and built, both in companies and academic labs (Panussis *et al*., 1996), for the purpose of picking M13 plaques and/or plasmid-containing colonies from agar plates. These robots typically combined a vision system for

imaging plates, an algorithmic selection of "pickable" plaques or colonies, a picking mechanism that contacted each plaque/colony to harvest it, and an axis/gantry system that precisely located the picking device over the plaque/colony to be harvested and over the microtiter plate well to be inoculated. The implementation of these devices into high-throughput sequencing labs provided an automated solution to a very tedious process and enabled a greatly enhanced scale of operations, not to mention making a significant dent in wooden toothpick sales worldwide.

The advent of large-scale cycle sequencing necessitated improvements to thermal cycler design – faster temperature transitions, smaller footprints, and multiple blocks were all developed to address the needs of high-throughput labs. Again, this was an area where both academic and commercial entities contributed their own designs and concepts, most of which again centered around the 96 well (and later 384) microtiter plate format. Hand in hand with thermal cycler development was the genesis of injection-molded microtiter plates that included the use of plastics with low thermal deformation and improved heat transfer characteristics, as well as design aspects that enabled both manual and robotic handling.

4. Impact of industrial/academic collaborations

As mentioned previously, there were a number of key discoveries or applications of existing technology that provided further ease of automation for DNA sequencing and related processes. Many of these resulted from efforts in academic labs funded to provide technology development for the Human Genome Project (HGP) by federal agencies such as NIH and DOE. These discoveries, in turn, were further developed into commercial products by companies that either became interested in, or were created to supply reagents, instrumentation, and develop technology for DNA sequencing.

Tabor and Richardson (1995) published a report of a mutated Taq polymerase with a single amino acid change in its nucleotide-binding site that mirrored the amino acid present at this position in the viral T7 polymerase. This single amino acid change effectively eliminated the polymerase's incorporation bias of dNTPs over ddNTPs, allowing a significant reduction in the ddNTP concentrations in sequencing reactions. Also in 1995, Ju and Mathies reported the use of fluorescence resonance energy transfer (FRET) technology in the design of base-specific dye primers (Ju *et al*., 1995a,b), effectively transforming a technique long used in protein structure determination into a fluorescent labeling strategy for modern day DNA sequencing applications. Energy Transfer ("ET") dye primers, and later "Big Dye" dye terminators (Lee *et al*., 1997), significantly enhanced DNA sequencing by dramatically reducing the amount of input template required to produce high quality sequence patterns, based on the enhanced quantum yield obtained from energy transfer from donor to acceptor dyes. Ultimately, the combination of FRET-based ("Big Dye™") dye terminators and the active site-modified thermostable polymerase yielded the most readily automated combination of technologies, and presently experiences widespread use in automated DNA sequencing. Namely, dye terminators enable one reaction per template (instead of four reactions when using

dye primers), the modified enzyme allows faster thermal cycling (fewer cycles, shorter extension times), and easier reaction cleanup to remove unincorporated terminators (since the ratio of fluorescent labeled ddNTP terminators to dNTPs is significantly reduced).

In addition to the commercialization of these key sequencing chemistry improvements, during the time period 1997–2001, many large-scale sequencing centers partnered with commercial robotics vendors to devise custom robotics solutions for specific high-throughput processes (Oefner *et al*., 1996; Marziali *et al*., 1999). Several of these robots, or scaled-down versions, subsequently transitioned into products for the sequencing market. In general, these robots either used a centrally positioned, articulated robotic arm or linear conveyor belts with gantry-mounted grippers to position microtiter plates onto various stations (liquid handling, plate sealing, mixing, lidding/delidding, etc.) on the workspace, and utilized scheduling software to keep all stations as occupied as possible in order to maximize throughput.

It is important to point out the critical contribution of sample tracking via barcodes and databases to these efforts. Without these tools, large numbers of samples would require manual logging as they progress through the DNA workflow, ultimately limiting the throughput.

Ultimately, DNA sequencing technology implementation is only as good as the instrument on which separation and excitation/detection occurs. As such, much of the ability to automate DNA sequencing was enabled by the evolution of DNA sequencing instrumentation, which has been considerable since commercial introduction of the Applied Biosystems 370 A in mid-1980 (Mardis and Roe, 1989). Early sequencing instruments, while automated in terms of laser scanning, fluorescence detection, and data analysis, required much user interaction including gel pouring, gel loading, and manual assignment of sample lanes ("tracking"). Developments that enhanced the automation of these instruments included replacing slab gels with capillaries (eliminating gel pouring and tracking), capillary illumination with a nonscanning laser beam (eliminating the time required for side-to-side scanning), and providing onboard robotics that scan barcodes and automate loading directly from a microtiter plate stacker (eliminating nearly all manual intervention) (Mardis, 1999).

5. Advent of high-throughput integrated DNA sequencing automation systems

The recent commercial introduction of DNA sequencing instruments with very high sensitivity has enabled the latest round of integrated robotics that approach full automation – that elusive ideal often referred to as *DNA in, sequence out*. In some of these efforts, the conventional, microtiter plate-based approach has been abandoned in favor of capillary tubes (an ironic twist of fate, since originally glass capillaries were used for DNA sequencing reaction vessels prior to the introduction of polypropylene microcentrifuge tubes). In other efforts, such as our own, 384 well microtiter plates are being used to prepare a sufficient amount of DNA for

one sequencing reaction in each well and then directly sequencing that DNA in the same plate. Regardless of the approach, the combination of enzymology, fluorescent labeling technology, submicroliter pipetting capability, rapid thermal cycling (due to enhanced thermal transfer and fewer cycles for small volumes), and detection sensitivity are making more fully integrated robotics approaches possible.

These efforts fall short of a fully automated approach since some preliminary work is required to grow the subclones in culture and since the sequencing products ultimately are loaded and detected on a separate instrument. As yet, the elusive goal of full automation continues to be the focus of many academic and commercial efforts to miniaturize the DNA preparation, sequencing, separation, and detection processes, by a variety of approaches. The most successful of these efforts should provide us with the next generation of automated DNA sequencing instrumentation systems, hopefully in the next few years.

Short Specialist Review

Microelectrophoresis devices for DNA sequencing

Daniel J. Ehrlich, James H. Aborn, Sameh A. El-Difrawy, Elizabeth A. Gismondi, Roger Lam, Brian McKenna and Thomas O'Neil
Whitehead Institute, Cambridge, MA, USA

1. Introduction

Extensive applications in genomics and biomedicine remain inaccessible because of the current cost of DNA sequencing technology. Commercial capillary arrays enabled the Human Genome Project but currently define the, often, prohibitive cost structure of sequencing. Microelectromechanical systems (MEMS) have been proposed as one technical approach to a significant near-term advance.

The often-cited intrinsic advantages of the microdevice approach are the practical engineering of cross-channel sample injectors and very high density networks. The basic capability cross-injector is illustrated in Figure 1. Because the volume of sample that is caught in that area is very small, microfabricated devices have the ability to scale the sample consumed in a given experiment far below that of capillary devices.

The cost savings that would accrue from a practical implementation of nanoliter sample handling and injection would be an advance for biological applications. Much research is active in this area. The second main aspect of leverage for microdevice (electrophoretic) sequencing is massively parallel networks that would extend the productivity of systems beyond the, typically 96-lane, capability of commercial capillary arrays. Some substantial capability for MEMS electrophoresis systems was demonstrated in short devices by Paegel *et al*. (2002) (430-base reads in a compact 96-channel device) and Liu *et al*. (2000) (450-base reads in a 16-channel device). However, the cost model for de novo sequencing is very sensitive to read length, particularly when assembly costs are considered. Hence, for this application, the compromise in read length in short microdevices (when these devices are compared to capillary instruments) is not acceptable. Short microdevices might be considered for resequencing and genotyping applications. Koutny *et al*. (2000) demonstrated long read length (800-base reads in a single-channel device), however, in a very simple single-channel device.

Therefore, although some remarkable capability was demonstrated in the early systems, they did not attempt the combined parallelism, read length, and automation required to challenge the commercial capillary array machines. The current state

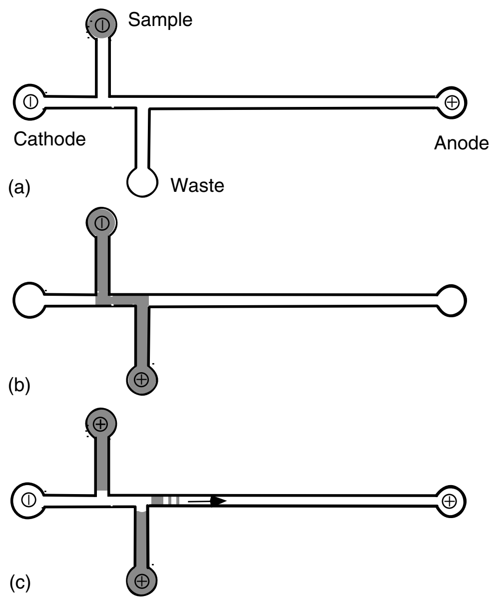

Figure 1 Schematic operation of a cross-injector used for DNA sample loading into a typical microdevice. The DNA sample is electrophoresed from the sample well to the waste well traveling, at least in part, through the separation channel. When the optimal loading time has been achieved, the voltages are switched, with the field now applied from one end of the separation channel to the other. This captures the DNA fragments that were in the separation channel at the time of the switch and begins the separation and detection process

of the art is now a 768-channel machine, which is in the final stages of testing and which is designed for exactly this purpose. The much more complex microdevice element is illustrated in Figure 2.

The factors that are most important in microdevice DNA sequencing are resolution and read length (Figure 3). The latter quantity includes consideration of the sample injection timing and the electrophoresis conditions. The ability to identify adjacent DNA fragments, particularly for large fragments, directly determines the performance and throughput characteristics of a given instrument. Because of the central importance of these parameters, each part of the instrument design is affected. The channel architecture cannot be permitted to add significant band broadening, and dense networks need to be robust to instabilities that occur in the network. Hence, the extension of single-channel performance to a dense network is nontrivial for long read applications.

2. Microdevice design and layout

A successful microdevice design must not only optimize conditions for fragment resolution and read length but must also take a number of other factors into account.The device design must have adequate space for the cross-injector elements, must be capable of interfacing with commercial sample introduction instruments (pipettors, capillary arrays, microtiter plates), must have channel separation lengths

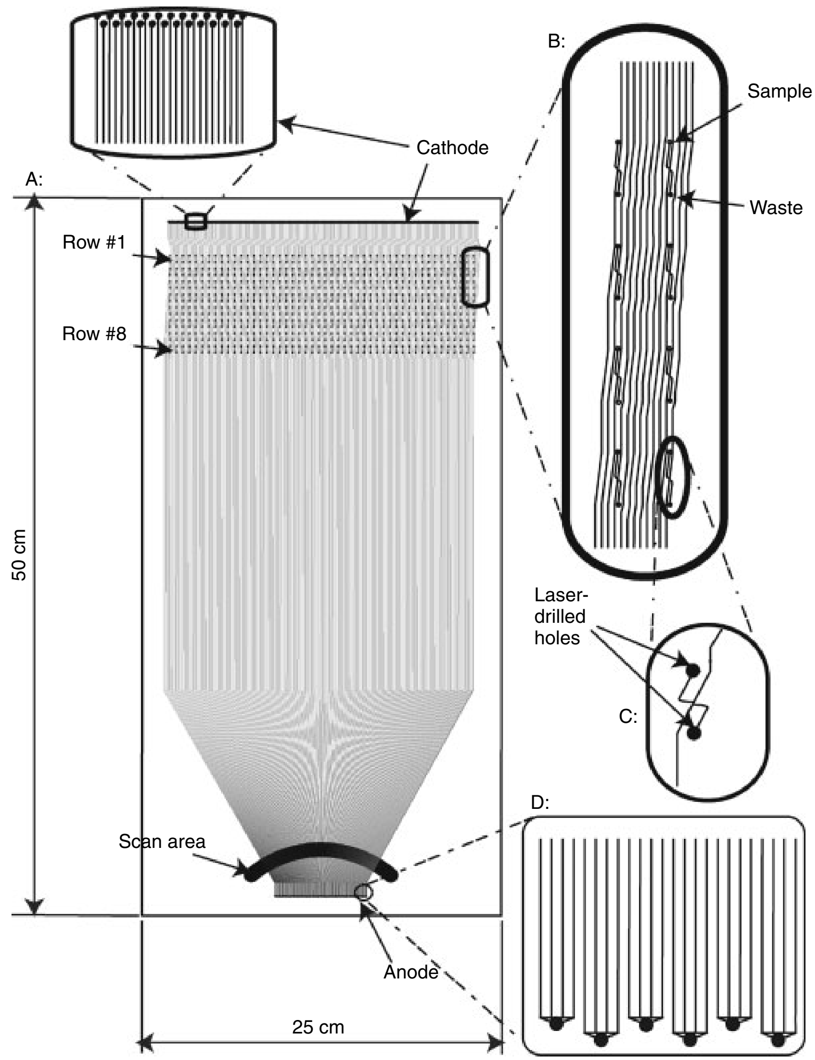

Figure 2 The plates contain 384 channels with double T cross-injectors and separation lengths varying from 37 to 45 cm. As the channels approach the detection window, they curve inward to achieve maximum channel density (~6 lanes/mm) during detection. This design provides full cross-injectors for all lanes, direct compatibility with commercial multitip pipettors, separation lengths optimized for long read performance, and channel geometry, which maximizes separation ability and lifetime

that allow for high quality, long read performance, and must minimize changes in channel direction, width, and/or cross section to maximize fragment resolution and device lifetime. Several devices have been constructed to this end.

A 16-channel device has been constructed that maintains channel length and minimizes the total size by allowing narrow turns in the device's separation channels. It has been reported that this device is capable of 450-base high-quality reads (Liu, 2000). Another device, a 96-lane microchip, does not have as extensive

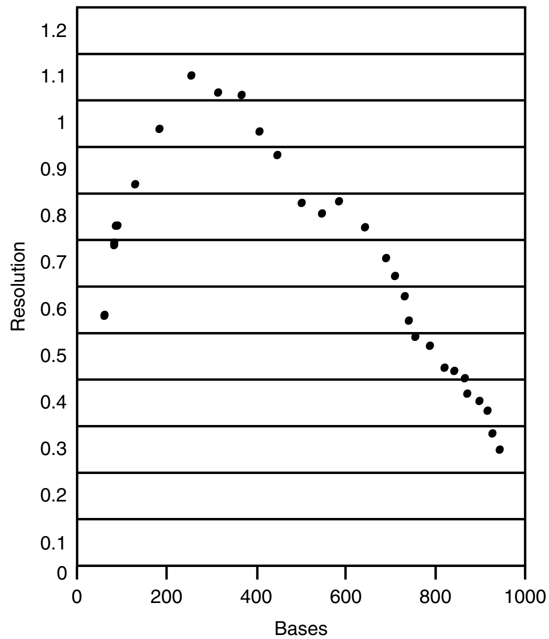

Figure 3 Resolution curve from a microfabricated single-channel sequencing device comparable to the high-quality performance of capillary machines. (Reprinted with permission from Koutny *et al*. (2000). ©2000 American Chemical Society)

separation lengths, but uses a radial design to maximize throughput capability and channel geometry consistency (Paegel, 2002). The 768-lane device mentioned earlier achieves long read length, >580 bases, and increased parallelism by using a large, 50 by 25 cm, substrate for device fabrication.

3. Microchip fabrication

These devices are created using standard and slightly modified microfabrication techniques on glass substrates described previously (Becker, 2000). Briefly, the glass substrates are coated with specialized photoresist and patterned via direct-write photolithography. Following this, the channels are etched into and access holes are drilled through the glass. Finally, two pieces of glass substrate are thermally fused.

4. Microchannel coating

Before the electrophoresis stage, the inner surfaces of the channels in the glass microdevice are usually chemically passivated to reduce or eliminate electroosmotic flow. Many different strategies have developed that often rely on the earlier work of Hjertén (1985) to form polymeric coatings for surface modification (Cobb, 1990; Fung, 1995; Madabhushi, 1998). These polymers can be attached to the channel wall either covalently or noncovalently. For glass microdevices, both covalent (Liu, 2000; Woolley, 1997; Shi, 1999) and noncovalent (Simpson, 2000; Backhouse, 2000) methods have been pursued extensively.

5. Separation media

The resolution and read length for a device are largely dependent on the media used for the fragment separation. Linear polyacrylamide (LPA) is used extensively as the separation matrix and is known for having high-quality sequencing ability (Koutny, 2000; Liu, 2000; Paegel, 2002). Several other media have been tested with varying degrees of success including polyethylene oxide (PEO) (Fung, 1995), poly(vinyl pyrrolidone)(PVP) (Song, 2001), hydroxycellulose (HEC) (Bashkin, 1996), and numerous mixed molecular weight and/or self-coating acrylamide copolymers (Sassi, 1996; Menchen, 1996; Dolnik, 2000).

6. Detection

Most microdevices for DNA sequencing use laser-induced fluorescence detection of tagged DNA fragments for detection. Many devices have a modified confocal scanner capable of exciting the fragments and collecting the emitted light (Dolnik, 2000; Woolley, 1997; Shi, 1999; Goedecke *et al*., 2004). Other detection systems use acousto-optical deflection-based laser beam scanners (Huang, 1999) and CCD cameras (Simpson, 2000).

Because of their inherent advantages, microdevices seem to be the next technological advance in high throughput DNA sequencing. Although there are certain drawbacks, such as the complex electrical networks being created, the sheer potential for parallelism and reduction in reagent costs are enormous.

Short Specialist Review

Single molecule array-based sequencing

Simon T. Bennett and Tony J. Smith
Solexa Limited, Little Chesterford, UK

1. Introduction

Hidden within an individual's genomic sequence are the genetic instructions for the entire repertoire of cellular components that determine the complexities of biological systems. Unraveling genomic structure and characterizing the functional elements from within the code will allow connections to be made between the genetic blueprint, transcribed information, and the resulting systems biology, and will, in turn, accelerate the exploration of the biological sciences.

As pointed out in a recent review (Shendure *et al*., 2004), the vast majority of known DNA sequence data to date have been generated using the Sanger-based sequencing method. However, genotyping (*see* Article 77, **Genotyping technology: the present and the future**, Volume 4) has been the tool most widely chosen for genetic exploration because the cost of sequencing individual genomes remains prohibitively expensive (recent estimates place the cost of sequencing a human genome in the region of tens of millions of US dollars). Technological advances in DNA resequencing, leveraging the availability of the consensus genome sequence for almost 200 species (**http://www.intlgenome.org/viewDatabase.cfm**), are transforming throughput and costs. An improvement in the region of four to five orders of magnitude over current sequencing costs is no longer an unrealistic prospect.

High-throughput sequence analysis, using capillary-electrophoretic separation and four-color fluorescent detection in instrument systems (such as the Applied Biosystems 3700/3730 and Amersham Biosciences MegaBACE 1000/4000), has been deployed successfully in factory-scale operations, largely within public-funded organizations, to sequence the human genome and that of many other species (*see* Article 5, **Robotics and automation**, Volume 3). Improvements in these systems continue to deliver incremental (maybe as high as 10-fold) increases in throughput and cost reductions. But these do not address the fundamental need for a transformation in cost-effectiveness that would be necessary for sequencing on a genome-wide scale to become a routine undertaking. Reagents are currently a highly significant cost element in current sequencing approaches and therefore a key target in cost-reduction approaches.

An initiative to address this key cost factor is being taken by the laboratory of Richard Mathies at U.C. Berkeley (Paegel *et al*., 2003). Mathies' lab is working

to achieve this goal by seeking to create an integrated microfabricated device that couples clone isolation, template amplification, Sanger extension, purification, and separation in a single microfluidic device. They highlight the development (in their lab and that of other workers) of highly parallel microfabricated capillary-array electrophoresis analyzers, nanoliter-scale DNA purification and amplification reactors, and microfluidic cell sorters and cytometers to support the feasibility of creating such an integrated microfabricated device. They calculate that the processing time could be reduced by 10-fold and reagent consumption by 100-fold, compared to the current state of the art. To go beyond this in cost reduction requires a fundamentally different strategy.

2. New sequencing approaches

There are several emerging sequencing technologies that aspire to ultralow cost, ultrahigh-throughput capabilities. Shendure *et al*. (2004) have classified these methods broadly into five different groups: microelectrophoretic methods (such as the work of Mathies and colleagues referred to above), hybridization, cyclic-array sequencing on amplified molecules, cyclic-array sequencing on single molecules, and real-time methods. While each of these approaches has potential to make the necessary breakthrough in technology, it is too early to predict whether expectations will be fulfilled. Yet, for some, and in particular the single molecule array-based approaches, recent developments have continued to stimulate community interest in sequencing technologies that have the capability to analyze entire genomes very quickly at an affordable price. This is particularly so for the human genome and the aspiration to achieve the so-called $1000 human genome concept (Zimmerman, 2004).

3. Single molecule–based approaches

Analysis at the single molecule level is challenging, yet it offers substantial advantages not only over conventional sequencing but also over other emerging technologies. Recent progress in the development of highly efficient strategies that dramatically reduce reagent consumption during analysis is bringing the routine analysis of whole-genome variation at the sequence level closer to reality. Methods under development, as reviewed by Smith (2004), fall into three main categories:

- *Single molecule separation:* Elongation of large fragments of genomic DNA that has been tagged with fluorescently labeled probes bound at specific sites, such as that being developed by OpGen (**http://www.opgen.com**) and US Genomics (**http://www.usgenomics.com**). The molecules can be analyzed at high speed, and this taken with the currently low (>1200 bp) resolution makes such techniques suited to mapping rather than sequencing.
- *Arrays of cloned single molecules:* Sequencing techniques related to high-density arrays of “colonies” of identical copies of template amplified from a single molecule, either immobilized on a solid surface (e.g., Solexa’s cluster array developed by former Swiss company Manteia) dispensed into a very high density

microtiter plate (e.g., 454 Life Sciences **http://www.454.com**), or amplified in a thin polyacrylamide gel matrix on a slide (e.g., George Church's group at Harvard; Mitra and Church, 1999).

- *Single molecule arrays:* Single molecule analysis in an array-based format to generate a massively parallel approach to sequencing, as pioneered by Solexa (**http://www.solexa.com**).

4. Single molecule array-based approaches

Single molecule array-based approaches are characterized by a number of distinct advantages over other technologies (Figure 1). In addition to minimal sample preparation and a novel sequencing chemistry, the rapid detection of single, fluorescently labeled dye molecules with very high signal-to-noise ratio is a critical feature of Solexa's Single Molecule Array™ (SMA) technology. The technology is massively parallel with an estimated 100 million single molecules of DNA sample template, dispersed randomly, per square centimeter of array. In the presence of a proprietary polymerase, specially designed nucleotides act as reversible terminators of sequencing so that, at each cycle, only a single base of DNA template is sequenced. Each of the four nucleotides is labeled with a distinguishable fluor and detected using a four-color detection system. Once the base has been identified, the block to further extension is relieved and the fluorescence removed so that the next cycle can be performed. Development of reversibly terminating nucleotides, by limiting each cycle to a single incorporation, overcomes the problem encountered by other approaches of having to decipher homopolymeric sequences and increases the accuracy of incorporation by the polymerase as all four nucleotides are present in the sequencing reaction.

The number of cycles of sequencing is dictated by the size of the genomic template that is under investigation. For example, with human resequencing, each template is sequenced to a length of 25 to 30 bases, derived from an analysis by Solexa of the human genome that revealed that unique alignment requires a read length of approximately 20 bases. Software aligns the n-mer reads against the reference sequence of the genome to identify a large part of the variation between

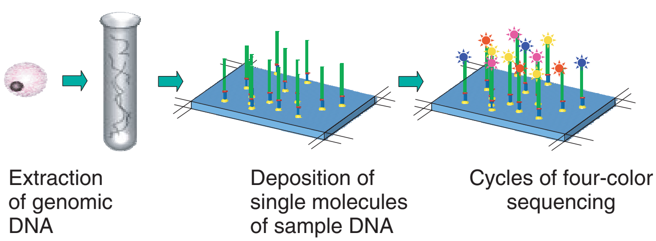

Figure 1 Single molecule array sequencing. Arrays of single molecules are created by binding randomly fragmented genomic DNA to a chip surface as primed templates. Addition of fluorescently labeled nucleotides and DNA polymerase allows sequence determination. (Reprinted from *Drug Discovery Today: Targets*, Volume **3**, Number 3, Smith T, Whole genome variation analysis using single molecule sequencing, 112–116, Copyright (2004), with permission from Elsevier)

the individual's DNA and the reference sequence. In this way, unknown SNPs as well as known SNPs can be detected and typed simultaneously at the same time as gathering data to determine haplotype structure and patterns of linkage disequilibrium. The approach is universally applicable to any organism for which a reference sequence is available, and shorter read lengths can be used where the genome, or a genome entity, such as a single chromosome, is less complex.

As the cost of sequencing per se is reduced, sample preparation will account for a significant proportion of total costs (*see* Article 4, **Sequencing templates – shotgun clone isolation versus amplification approaches**, Volume 3). Performed in a single reaction, the SMA approach does not require costly or time-consuming preparation, such as PCR amplification or cloning target DNA into bacteria. Another important advantage of SMA is the requirement only for very small quantities (picograms) of DNA starting material. This not only avoids averaging effects of using large samples, masking what is really happening in a biological system but also avoids representational bias by minimizing sample processing. These features, together with a dramatic reduction in reaction volume, combine to revolutionize the economic landscape of sequencing. Once viable economically at large scale, whole genome resequencing of each sample will enable true whole-genome association studies.

A critical consideration is that these new approaches will produce an unprecedented quantity of data, which will have to be processed, annotated, and applied. This will require an entirely new set of skills, systems, and databases, which, it is anticipated, will create an entirely new field of genomics. To this end, Solexa is working with the groups of Ewan Birney and Richard Durbin at the European Bioinformatics Institute and the Wellcome Trust Sanger Institute, respectively, to extend and advance the *Ensembl* system (**http://www.ensembl.org**) to manage, query, and visualize multiple whole-genome sequence data sets. Furthermore, as a second strand to this project, statistical methods and tools are being developed with David Balding and colleagues at Imperial College London to allow epidemiological studies to exploit whole-genome data to localize gene effects involved in disease susceptibility and drug metabolism.

5. Arrays of cloned single molecules

There is a group of related techniques that seeks to overcome the high sensitivity required to analyze individual single molecules, by creating a high-density array of "colonies" of identical copies amplified from a single molecule (Figure 2). George Church's group at Harvard (Mitra and Church, 1999; Mitra *et al*., 2003) carry out PCR amplification in a thin polyacrylamide gel matrix on a slide to constrain lateral diffusion, thereby creating colonies of PCR products; they coined the term "polonies" to describe these. A related strategy, Manteia approach (Adessi *et al*., 2000), involved amplification of single-molecule templates immobilized on a solid surface. 454 Life Sciences (Leamon *et al*., 2003) have dispensed single molecules into a very high density microtiter plate, such that each 75-picoliter well contains no more than one molecule, and then carried out amplification. The sequences of several viral and bacterial genomes have been determined using this approach.

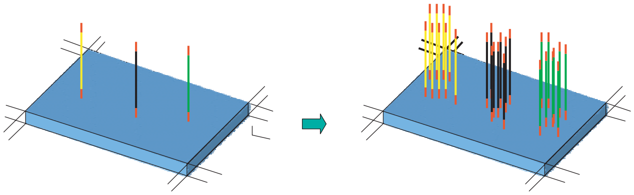

Figure 2 Arrays of cloned single molecules. Single molecules are amplified in a spatially defined way such that a large number of identical copies of each are generated in isolated "colonies". These colonies can then be subjected to sequencing in situ. (Reprinted from *Drug Discovery Today: Targets*, Volume **3**, Number 3, Smith T, Whole genome variation analysis using single molecule sequencing, 112–116, Copyright (2004), with permission from Elsevier)

These arrays of cloned single molecules are then subjected to sequencing using, for example, DNA polymerase–based incorporation of labeled nucleotides and fluorescence detection or pyrosequencing (**http://www.pyrosequencing.com**). The use of cloned single molecules facilitates detection by yielding a higher signal than an individual single molecule. In principle, this allows detection instrumentation that is relatively less sophisticated and less costly to be employed. A somewhat greater level of inefficiency in the sequencing biochemistry or loss of templates through the process can be tolerated, as the signal is derived from a large number of molecules. Balanced against these considerations, cloned single molecules can introduce problems owing to the individual molecules in a colony becoming out of phase with one another during the sequencing process and therefore creating high backgrounds and spurious signals. Other issues are the complexity and effort involved in generating the cloned array and the potential for the sequence representation of the sample not to be faithfully preserved.

6. Applications

By applying different simple methods of sample preparation and downstream analysis algorithms to the core technology, the range of capabilities of SMA technology is extended. SMA can be applied either to resequence whole genomes or to the same reproducible, specific genome sequence from several different individuals to provide a particular set number of SNP loci (e.g., a particular subset of, say, 1 million SNPs) for mapping traits (Bennett, 2004; *see also* Article 11, **Mapping complex disease phenotypes**, Volume 3 and Article 17, **Linkage disequilibrium and whole-genome association studies**, Volume 3).

The primary application focus is on basic research, both in academia and in industry, where this breakthrough technology is anticipated to stimulate a new wave of research activity enabled by the newfound ability to measure variation comprehensively across whole genomes (*see* Article 68, **Normal DNA sequence variations in humans**, Volume 4). The technology will stimulate new methods of applying knowledge of individual variation with wide-ranging applications, such as is in functional/comparative genomics (*see* Article 48, **Comparative sequencing**

of vertebrate genomes, Volume 3), exploration of microbial diversity for the agricultural biology field, pathogen identification (*see* Article 49, **Bacterial pathogens of man**, Volume 4), transcriptome characterization and in particular of alternative splice variants, genotype–phenotype correlations, human and animal disease association (*see* Article 57, **Genetics of complex diseases: lessons from type 2 diabetes**, Volume 2), pharmacogenomics, the development of new molecular diagnostics and drugs, and in personalized medicine. This process will begin largely in the major government-funded and not-for-profit-funded research institutes, leveraging the strong political will that exists to see real human health benefits from the large investment already made in genetics, and in particular in the Human Genome Project (*see* Article 24, **The Human Genome Project**, Volume 3) and its various ramifications.

7. Concluding remarks

Single molecule array-based sequencing technology has the potential to transform the economics of DNA sequencing by allowing the sequence of hundreds of millions of individual molecules to be determined rapidly in parallel. The approach drastically reduces, and at best obviates, the need for sorting, cloning, and amplification of genomic DNA samples with the consequential reduction in laboratory preparation and reagent overheads. Together, these facets of single molecule array-based sequencing will allow sequencing of large entities genomic, including whole genomes, at costs several orders of magnitude below current levels. For human genetics, next-generation technologies such as SMA offer the potential to achieve the much sought after $1000 human genome goal.

Short Specialist Review

Real-time DNA sequencing

Susan H. Hardin
University of Houston, Houston, TX, USA

1. Introduction

DNA sequence information provides insights into a wide range of biological processes. The order of bases in DNA implies the order of bases in RNA and, consequently, the amino acid sequence of protein. DNA sequence specifies a molecular program that can lead to normal development or the manifestation of a genetic disease such as cancer. DNA sequence information also has the potential to instantly and conclusively identify a pathogen (or variation thereof), or uniquely identify and genetically characterize an individual.

The core elements required for DNA replication in a test tube include DNA polymerase, deoxynucleotide triphosphates, template, and primer in a buffer that promotes the activity. DNA synthesis occurs when the primer's 3′-end attacks the α-phosphate of the incoming nucleotide, which is complementary to the template strand. Of the three phosphates within the nucleotide, only the α-phosphate becomes part of the DNA strand. The β- and γ-phosphates (pyrophosphate, PP_i) are released into the solution.

Approximately 30 years ago, Sanger and colleagues developed a sequencing method that exploited the basic biochemistry of DNA replication (Sanger *et al*., 1977). Of particular importance for their method are the facts that DNA polymerase can incorporate a dideoxynucleotide triphosphate (ddNTP; a nucleotide analog lacking a 3′ OH), and that, once incorporated, additional nucleotide incorporation is not possible. Importantly, ddNTPs are incorporated by the polymerase using the same base incorporation rules that dictate incorporation of natural nucleotides. The reaction products are size-separated and examined to deduce the DNA sequence information.

The first human genome was sequenced using variations of Dr. Sanger's chemistry and important breakthroughs in instrumentation and process automation (Lander *et al*., 2001; Venter *et al*., 2001). This first human genome sequence has sparked a new era in genome analysis. Identifying differences in the genetic code that make each of us unique is the next challenge. Given current cost estimates of \$10–\$25 million to sequence a single human genome, it is unlikely that the large numbers of human genomes needed to identify these important differences will be completed using Sanger-based sequencing methods, and even less likely that this chemistry will be used to enable the promise of whole genome analysis for medical purposes (personalized medicine).

The desire to examine differences between genomes is so great that an industry directing analysis to regions previously associated with genetic variation has emerged. Single nucleotide polymorphism (SNP) analyses essentially involve skimming genomic information from predetermined regions owing to cost limitations and time constraints of current DNA sequencing methods. Ultrahigh throughput sequencing will enable a more comprehensive form of genetic variation detection that does not begin with assumptions. The fundamental importance of DNA sequence information drives researchers to continually strive to improve the efficiency and accuracy of sequencing methods.

2. A massively parallel, real-time sequencing strategy

We are developing a sequencing platform that will enable a more comprehensive form of genetic variation detection. Cutting-edge technologies, including single-molecule detection, fluorescent molecule chemistry, computational biochemistry, and biomolecule engineering and purification, are being combined to create this new platform. Our approach may make it easier to classify an organism or identify variations within an organism by sequencing the genome in question.

The basic biochemistry of DNA replication is being exploited in a new way to develop a radically different method to sequence DNA. DNA polymerase and nucleotides triphosphates are being engineered to act together as direct molecular sensors of DNA base identity at the single-molecule level. The general strategy involves monitoring real-time, single-pair fluorescence resonance energy transfer (spFRET) between a donor fluorophore attached to a polymerase and a color-coded acceptor fluorophore attached to the γ-phosphate of a dNTP (5′ fluorescently modified γ-phosphate) during nucleotide incorporation and pyrophosphate release (Figure 1). The purpose of the donor is to stimulate an acceptor to produce a characteristic fluorescent signal that indicates base identity (emission wavelength and intensity provide a unique signature of base identity). Equally important to our technology are the massively parallel arrays of nanomachines created to produce the unprecedented throughput of the sequencing system. Projected sequencing rates approach 1 million bases per second – rather than per day – per instrument; almost a 100 000-fold increase over current throughput.

The sequencing platform incorporates a laser that is tuned to excite the donor fluorophore. A spFRET-based strategy increases signal-to-noise by minimizing acceptor emission until the acceptor fluorophore is sufficiently close to a donor fluorophore to accept energy. Incorporating total internal reflectance fluorescence (TIRF) into the platform further increases signal-to-noise, since most of the labeled dNTPs in solution are not within the TIRF excitation volume and are, therefore, not directly excited by the incident light.

As an acceptor-labeled dNTP approaches the donor-labeled polymerase, it begins to emit its signature wavelength of light owing to energy transfer from the donor (they participate in spFRET), and the intensity of this fluorescence increases throughout the nucleotide's approach. The molecules are engineered to maximally

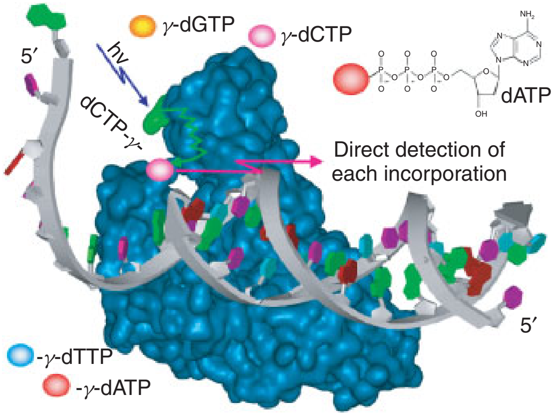

Figure 1 Real-time detection of dNTP incorporation. Components of the VisiGen Sequencing System include modified polymerase, color-coded nucleotides, primer, and template. Energy transfers from a donor fluorophore within polymerase to an acceptor fluorophore on the γ-phosphate of the incoming dNTP, stimulating acceptor emission, fluorescence detection, and incorporated nucleotide identification. Fluorescently tagged pyrophosphate leaves the complex, producing natural DNA. This nonserial approach enables rapid detection of subsequent incorporation events. Time-dependent fluorescent signals emitted from each complex are monitored in massively parallel arrays and analyzed to determine DNA sequence information. Courtesy of Dr. Tommie Lincecum, VisiGen Biotechnologies, Inc

FRET after the acceptor-dNTP docks at the active site of the polymerase (within the nucleotide binding pocket). During nucleotide insertion, the 3′ end of the primer attacks the α-phosphate within the dNTP, cleaving the bond between the α- and β-phosphates, and changing the spectral properties of the fluorophore (which remains attached to the PP_i). Donor fluorescence is also informative, as it undergoes anticorrelated intensity changes throughout the incorporation reaction. As the acceptor-tagged PP_i is released from the polymerase, the distance between it and the donor fluorophore increases, causing the intensity of the acceptor's fluorescence to decrease and that of the donor's to simultaneously increase. After an spFRET event, the donor's emission returns to its original state and is ready to undergo a similar intensity oscillation cycle with the next acceptor-tagged nucleotide. In this way, the donor fluorophore acts as a punctuation mark between incorporation events. The increase in donor fluorescence between incorporations is especially important during analysis of homopolymeric sequences.

Acknowledgments

Development of VisiGen's sequencing platform has been funded by DARPA and NIH in support of national defense (to identify pathogenic organisms or variations thereof) and to enable comprehensive genome analysis (basic science discovery and personalized medicine), respectively. Discussions with VisiGen development teams are gratefully acknowledged.

Introductory Review

Genome mapping overview

Wesley C. Warren and Michael Lovett
Washington University School of Medicine, St. Louis, MO, USA

1. Introduction

True physical maps, for example, fingerprint maps in which each clone is "fingerprinted" on the basis of the pattern of fragments generated by a restriction enzyme digest, of large-insert molecular clones have had a tremendous impact upon large-scale genomic DNA sequencing. The physical map of the human genome (McPherson *et al*., 2001) provided the necessary scaffolding for accurate final compilation of the human genomic DNA sequence. Computationally deconvoluting an entire shotgun sequence of small DNA fragments from large genomes is challenging, some more so than others. These final assembly steps are immeasurably helped by the availability of an ordered set of markers or molecular clones. Reference sets of ordered molecular clones have also impacted many other fields. For example, the use of mapped bacterial artificial clones (BACs) for array-based comparative genomic hybridization (CGH) (Ishkanian *et al*., 2004), and the use of mapped BACs to identify chromosomal rearrangement breakpoints (Volik *et al*., 2003) are just two of the many mapping spin-offs that have become widely used tools for disease analysis and gene discovery.

2. Genetic maps

Genetic linkage maps have provided a key framework for all of the mammalian genomes that currently have published draft DNA sequence assemblies. Genetic maps were first constructed in the early twentieth century (Morgan, 1910) and preceded all other map construction methods. These early maps started with the meiotic mapping of chromosome landmarks, as defined by phenotypes such as eye color in flies. They next moved to biochemical markers such as blood antigens or isozymes and finally evolved into our current use of multiple allelic polymorphic DNA markers. These markers are commonly referred to as simple sequence repeats (SSR) and single-nucleotide polymorphisms (SNP). Even today, the markers that initially anchored the first crude linkage maps sometimes still serve as the basis for defining quantitative trait loci (QTLs) in agriculturally relevant species and in organisms used as human disease models. The basic premise for building a genetic map from polymorphic DNA markers has not changed, and involves the

typing of a sufficient number of multiple allele markers in a defined population and use of standard quantitative genetic formulas to place markers into ordered linkage groups. The SSR-based linkage map has been the traditional choice for linkage analysis studies, whereas SNP maps are more commonly used in association studies (see review; Blangero, 2004). Linkage analysis attempts to define alleles within chromosomal regions that are identical by descent in a pedigree or set of pedigrees, using phenotypic data to infer this relationship. Association analysis, in contrast, does not necessarily rely on related individuals but instead tests the frequency of an observed genotype on the distribution of phenotype across a large population. Both methods rely on linkage disequilibrium between the observed alleles and the quantitative trait of interest. Several groups have successfully used a combination of linkage and association methods to link genotype to disease causation (Styrkarsdottir *et al*., 2003; Helms *et al*., 2003; Pajukanta *et al*., 2004).

In the past decade, the development of large-model organism-specific SNP databases has provided the impetus to design whole-genome association studies to infer the existence of heritable QTLs. These studies may suffer from large stochastic variances in linkage disequilibrium and may thus require large numbers of SNPs, estimates range from 200 000 to 1 million (Carlson *et al*., 2004). Although these are daunting numbers, if costs and throughput continue on the current trend, we anticipate that the use of large whole-genome SNP panels will become a routine method for the discovery of candidate QTL or disease-associated regions, especially for complex diseases. The availability of a human haplotype map (which will catalog the more common haplotype blocks in humans (The International HapMap Consortium, 2003) will further augment these association studies by enabling us to more efficiently design mapping studies on samples of different ethnic origin. It appears inevitable that the construction of whole-genome genetic linkage maps will decline in nonmodel and non-food-producing organisms, and they are certainly not absolutely required to derive a finished genomic DNA sequence. However, it seems likely that they will continue to be used in defining the etiology of heritable traits in many plants and animals. It is also likely that the successful use of SNPs in association studies of complex human disease will require improvements in the collection and quantitation of many phenotypic parameters for very large sample sets (Bell, 2004). In the end, even association studies can only pinpoint a region, an SNP or set of SNPs that is associated with increased disease risk. Improvements in the targeted resequencing of large genomic regions will be necessary to uncover all of the DNA variation that exists in affected individuals.

3. Physical maps

Physical maps are relatively new and have advanced rapidly in the last decade owing to advances in clone manipulation and high-throughput automation. Physical mapping (the positioning of molecular clones along a genome) has been a central technology in deriving a finished genomic DNA sequence for many genomes. Most notably, the high-quality DNA sequence of the human and many other model organism genomes has greatly accelerated our ability to map a phenotype of interest to a defined chromosomal region. A plethora of physical mapping techniques exist

and fall into three general categories: (1) cytogenetic characterization, in which fluorescent in situ hybridization (FISH) is the most used method, whereby markers are localized along a defined chromosomal axis (Heng *et al*., 1997); (2) radiation hybrid mapping, in which hybrid cell lines randomly segregate chromosome fragments. These fragments can then be ordered by the PCR amplification of specific markers across a panel of cell lines (Cox, 1992); and (3) restriction mapping, which relies on random distribution of restriction enzyme sites in a genome (Olson *et al*., 1986; Coulson *et al*., 1986; Marra *et al*., 1997).

Improvements in the resolution of FISH techniques have come from higher-resolution microscopy, more efficient dye labeling methods and improved template preparation, such as interphase nuclei FISH and fiber-FISH (Florijn *et al*., 1995). Molecular cytogenetics has experienced a resurgence in recent years with the modification of methods such as spectral karyotyping SKY (Weimer *et al*., 2001), and the advent of comparative genomic hybridization CGH (Kallioniemi *et al*., 1992). These have had a particular impact upon cancer (see review; Heng *et al*., 2004), but new methods such as array CGH (a fusion of CGH, large-insert genomic clones and microarray technologies; Pinkel *et al*., 1998) are providing insights into copy number changes in many other complex diseases. Radiation hybrid (RH) maps, as briefly mentioned above, evolved as a result of the need to improve marker resolution over genetic maps and to not rely on polymorphisms to order markers along a chromosomal axis. The use of RH maps for anchoring sequences along a chromosome and constructing synteny relationships among species is now well documented (Mouse Genome Sequencing Consortium, 2002; International Human Genome Sequencing Consortium, 2001). Another method related to RH mapping is HAPPY mapping, although to date its use has been relegated to chromosomes and not to whole-genome maps (Thangavelu *et al*., 2003). In this case, the segregation of markers is conducted entirely in vitro by randomly breaking DNAs and subpartitioning the DNA into smaller samples. The frequency of two markers being retained in any sample is proportional to their relative physical distance (as in RH maps). Thus, HAPPY mapping, like genetic maps and RH maps, relies upon statistical methods for marker ordering.

Maps have guided the genomic DNA sequence assemblies of many eukaryotic organisms. Sometimes, the phylogenetic relationship of a particular organism is so close to an already existing map from another species that organization of assembled sequences is relatively straightforward. One example of this would be the relationship of chimpanzee sequence assemblies to the sequenced human genome. However, even in this case, when utilizing known syntenic and karyotypic relationships between the two species, care was exercised so as to avoid "humanizing" the chimpanzee sequence. In general, some form of framework map is required as a scaffold on which to assemble the final consensus sequence, and this map becomes very important when duplications or gaps must be resolved. High-quality physical maps require the ordering of reference markers along a definable linear track. Frequently, this track has consisted of restriction enzyme cleavage points. Two predominant techniques have been employed in these types of maps; clone-based restriction enzyme fingerprinting methods and, to a lesser extent, optical mapping of restriction fragments. Fingerprint maps have aided the accurate sequence assembly of the human, mouse, rat, and chicken genomic DNA sequences

(Meyers *et al*., 2004; Wallis *et al*., 2004). In essence, they rely upon inferring large-insert clone overlaps and relationships by matching patterns in the lengths of various restriction enzyme digestion products. Optical maps, which depend upon stretching out DNAs and visualizing the length and order of various restriction enzyme digestion sites, have been helpful in quickly establishing genome order for relatively small genomes (Zhou *et al*., 2003) but suffer from the inability to actually archive a given stretch of DNA for further analysis. Whatever mapping method is employed, the lessons to date indicate that for most large genomes, once a draft genomic DNA sequence is achieved, it is necessary to validate the assembly by reconciling marker orders with some form of reference physical map.

4. Mapping informatics

For practitioners of map building and the use of maps in the genetic dissection of complex phenotypes, the main objective of informatics must be to present a great deal of information in a simple visualizable format. Typically, there are two definable stages associated with the positional cloning of candidate genes for a trait of interest. At early stages, a framework map of some type is routinely required to navigate even closer to the variant allele or haplotype block. Once an interval is roughly defined, additional genetic mapping accelerates progress toward higher interval resolution and potential candidate gene isolation. There are now numerous algorithms and software choices for how to accomplish this phase for quantitative trait loci in experimental model organism crosses, human pedigrees or human populations (see **http://linkage.rockefeller.edu/soft/list.html** for examples).

Comparative genomic analysis has become particularly important and powerful in defining genes and putative regulatory elements across species. There are now many such tools available for human and mouse genetics (many of which can be accessed through NCBI). One much favored entry point to these tools would be the UCSC genome browser and associated tools. However, many other software tools exist for the comparative evaluation of genetic and physical maps. For example, the package CMap (an extension of the genome model organism database (GMOD) project (**http://www.gmod.org**)) was originally written for map integration of various plant species, but it has pushed investigators toward common platforms, thus allowing experiments to quickly move from an in silico analysis to the bench or to the field. Likewise, the availability of FPC software has been pivotal in advancing the construction of fingerprint maps in numerous species (e.g., Soderlund *et al*., 1997). Improvements to FPC and additional independent mapping software have moved the physical mapping process from labor-intensive to highly automated in a short period of time (see **http://www.bcgsc.ca/bioinfo/software/** for software examples). For newly sequenced genomes, we expect that software development will continue to play a pivotal role in integrating map and sequence assemblies.

5. Conclusions

It is clear that maps have played a key part in assembling the linear order of sequenced genomes. They continue to provide the framework on which the genetic

dissection of complex phenotypes is based. However, just like geographic map projections of the world, they can contain distortions and ambiguities. Among these are the degree to which duplications, rearrangements, and deletions occur as common events throughout many genomes (including our own). Maps will continue to evolve and improve, in combination with overlayed information on transcription, regulation, and epigenetic levels of genomic control. It is hoped that the lessons of the past, in which even low-resolution framework maps played significant roles, will continue to be applied to future large-scale genomic DNA sequencing projects.

Introductory Review

Linking DNA to production: the mapping of quantitative trait loci in livestock

Stephen S. Moore, Christiane Hansen and Changxi Li
University of Alberta, Edmonton, AB, Canada

1. Introduction

The world's livestock populations provide a considerable resource with which functions can be assigned to genes. Unique populations have resulted from centuries of genetic selection focused on specific traits such as milk or meat production, fertility, and conformation, to name a few. Livestock production is of significant economic importance worldwide, and animal breeders and geneticists alike have historically been interested in linking the genetic makeup of an animal with its production. While the accuracy of traditional methods of selection is high, selection for certain traits can be limited by the fact that they can only be measured in one sex or are difficult to measure in a production setting. For these traits, molecular technologies can help improve the accuracy of their selection.

The majority of the traits of interest for the various livestock sectors are quantitative in nature in that they are controlled by many genes. Quantitative trait loci (QTL) are areas of the genome that affect a quantitative trait. A QTL may contain one or a number of genes affecting a specific trait. The size of the effect will vary depending on the gene and the trait involved. Our ability to identify QTL is a function of the size of the gene effect, the family or population structure under study, and the density of informative DNA marker information available. DNA marker information, compiled in the form of genetic linkage maps, is currently available for all of the major livestock species (Barendse *et al*., 1997; Kappes *et al*., 1997; Rohrer *et al*., 1996; De Gotari *et al*., 1998; Groenen *et al*., 2000).

DNA markers generally fall into two categories. The first category includes highly informative, multiallelic markers, of which *Simple Sequence Repeats* (SSRs or microsatellites) are the most widely used for genetic and QTL mapping in livestock. SSRs are hypermutable, which has resulted in multiple alleles segregating in any population. Studies using these markers have generally been restricted to within families, rather than populations, where the genetic phase, the specific allelic association with the trait, can be determined. This, in turn, has meant that in species such as cattle, QTL segregating in only a limited number of individuals, usually the sires or grandsires of families, have been studied.

The second type of marker is the *Single Nucleotide Polymorphism* (SNP). These markers are usually biallelic and much less mutable than SSRs. Studies using SNPs may be carried out in animal populations rather than families, allowing the analysis of many more individual genomes than is otherwise possible. SNPs promise to revolutionize the way in which QTL mapping is carried out in livestock species, promising both more rapid and sensitive approaches.

2. QTL mapping in livestock species

The majority of research in QTL identification has been carried out in cattle (dairy and beef) and swine. In both species, work has centered on traits that are of importance for production or product quality. For dairy cattle, the work has focused on milk production and quality-associated traits (e.g., Freyer *et al*., 2002; Olsen *et al*., 2002), while for beef cattle (see Table 1) and swine (e.g., Andersson-Eklund *et al*., 1998; Varona *et al*., 2002), the focus has been on growth and carcass-related traits. Work has also been done in both species to identify, among other things, QTL associated with reproductive, behavior and health-/disease-related traits (e.g., Desautes *et al*., 2003; Kuhn *et al*., 2003).

Table 1 Examples of QTL reported in the literature for several growth- and meat-quality traits in beef cattle

[b]Actual effect.
n/a: Not available.

In chickens, the research focus has been primarily divided between the discovery of QTL underlying egg production-associated traits and growth/carcass/meat production-related traits (e.g., de Koning *et al*., 2003). Some research has also been carried out in identifying genes associated with disease, for example, Marek's disease (Yonash *et al*., 1999).

Experiments to discover QTL in sheep are more limited. For example, Beh *et al*. (2002) have performed a genome scan to identify QTL for resistance to the intestinal parasite *Trichostrongylus colubriformis* in sheep, and Rozen *et al*. (2003) have identified QTL associated with milk production traits.

3. Genes underlying QTL

While a significant amount of research has been done on QTL detection in livestock species, very few genes underlying the various QTL have actually been identified. Several examples are listed in Table 2. The limitation in identifying the genes has been due largely to the resolution of QTL mapping attainable using the current interval mapping approaches. Most regions identified as housing QTL have been in the order of 20–50 cM in length. This can approximate to as many as 50 million bases. The fact that such an interval can house thousands of genes, plus the fact that comparative maps with more well-studied genomes have until recently been rudimentary, has made it difficult to move from QTL regions to the genes themselves. More recently, Identity by Decent (IBD) methodology has been used to successfully narrow down QTL regions, and, in some cases, identify genes underlying QTL (Farnir *et al*., 2000; Moore *et al*., 2003; Li *et al*., 2002, 2004; *see also* Article 12, **Haplotype mapping**, Volume 3). This approach uses the historical recombination that has occurred over many generations within a given population, rather than the recombination observed within two or three generations in a family. The limitation has now become the reliance on SSR markers and the accompanying uncertainty regarding phase in wider populations. The use of the more stable SNP markers will greatly improve our ability to fine map genes.

Table 2 Examples of genes underlying or associated with QTL in livestock

Leptin	Fatness (cattle)	Buchanan *et al*. (2002)
Estrogen receptor	Litter size (pigs)	Rothschild *et al*. (1996)

4. Future directions

The vast majority of the QTL work that has been done to date has relied on microsatellite markers coupled with interval mapping approaches. In order to fine-map many of the QTL that have been identified, SNP markers coupled with populationwide IBD methodologies will prove useful in the future. Linkage disequilibrium mapping (Jorde, 2000) also holds great promise in this regard. The completion of the bovine sequence and the analysis of the data generated will make application of these various techniques more feasible in the future.

Specialist Review

Mapping complex disease phenotypes

David A. Collier
The Institute of Psychiatry, London, UK

1. Introduction

Complex medical conditions such as obesity and diabetes, and psychiatric disorders such as depression and schizophrenia, are common disabling diseases. Their aetiology involves genetic factors, the environment, and their interaction, with genes typically explaining half or more of the variance. A complete model of causation would include all genetic and environmental factors, and their joint effect on risk of illness. Genetic mapping of complex disease phenotypes focuses on identifying just one component of a complex causal system, the role of genes (*see* Article 58, **Concept of complex trait genetics**, Volume 2).

The genetic factors involved in complex disease phenotypes are likely to be risk alleles that are relatively common in the population, but have a modest effect on risk, that is, they exert a weak genetic effect. This is in contrast to high-risk alleles, which have been found only rarely in complex disorders.

For example, more than 55 high-risk alleles for obesity have been identified in a total of six genes, but these are present in less than 2% of the obese population, and most are found in single families (Obesity gene map database; **http://obesitygene.pbrc.edu/**). Likewise, more than 150 rare high-risk alleles have been identified for Alzheimer's disease, but their population attributable fraction is only 5%. This is in contrast to the *APOE4* gene, which as a common, modest risk factor has a population attributable fraction of 20%. Rare high-risk alleles have been very valuable in unraveling the underlying aetiological pathways in diseases such as obesity and Alzheimer's disease, but for other diseases such as depression and schizophrenia, such rare high-risk alleles have been elusive.

Common, modest risk alleles are likely to be substantially more important than rare high-risk alleles in efforts to improve our understanding of aetiology and the identification of novel treatments. However, different methods are required for their identification as the tools used for identifying high-risk alleles have not been successfully applied (Cardon and Bell, 2001; Risch, 2000).

2. Linkage analysis

2.1. Linkage in complex phenotypes

The most successful method for identifying genes for human disorders has been linkage analysis, which uses families with the disorder to search for the cosegregation or sharing by affected members of genetic markers (*see* Article 15, **Linkage mapping**, Volume 3). It is reliant solely on the genetic analysis of the phenotype, avoiding the need for prior information on pathophysiology and the function of potential risk genes. Linkage analysis has been successful in the identification of genetic loci for many human genetic diseases, and in animal models of disease. It has substantial power for rare, highly penetrant risk alleles such as those in single-gene disorders, however, power is reduced for complex diseases, where risk alleles only have a moderate effect on risk (meaning that allele sharing between affected subjects will be much less evident), and which are influenced by environmental factors. In addition, classical parameters used for mapping Mendelian diseases relating to the mode of inheritance (dominant, recessive) cannot be readily applied as they are unknown for complex disorders (*see* Article 48, **Parametric versus nonparametric and two-point versus multipoint: controversies in gene mapping**, Volume 1). To overcome this, two approaches are typically taken to linkage in complex disorders: the nonparametric approach whereby parameters are abandoned and the analysis focused on sharing of alleles between affected family members, usually sibling pairs, or the retention of the likelihood method, with the approximation of parameters in a flexible frame work (Sham, 1997).

Steps in a linkage study involve identifying the phenotype, which can be a dichotomous trait such as clinical diagnosis, or a quantitative trait such as body mass index (BMI) or neuroticism; identifying and collecting DNA from the family samples; selecting a genetic marker map and genotyping; and data cleaning and statistical analysis of the data to search for evidence of linkage.

Linkage analysis in complex disorders using dichotomous traits such as disease diagnoses is relatively straightforward. In its simplest form, it measures allele sharing by affected relatives using identity-by-state or identity-by-descent methods, and uses a test statistic to evaluate the significance of deviation from the null hypothesis. A typical linkage marker set consists of 500 or fewer genetic markers spaced throughout the genome, formed into a genetic map; the most commonly used map is the Marshfield map (**http://research.marshfieldclinic.org/genetics/Default.htm**), but many others are available.

Various study designs can be used to increase power and reduce effort in linkage analyses. These apply particularly to quantitative traits. For example, sibships with the greatest expected contributions to a true LOD peak can be selected for linkage analysis by selecting extreme discordant or concordant sib pairs for the trait under study (Purcell *et al*., 2001; Carey and Williamson, 1991; Risch and Zhang, 1995). This approach may be very powerful and efficient when mapping quantitative traits in a large population, as genotyping will only be needed in a subset (Nash *et al*., 2004).

2.2. Data cleaning

After genotyping, data cleaning is used to check the integrity of the data; this is particularly important for testing family structures. For example, sibling pairs may in fact be half-siblings or even unrelated, and the presence of unspecified monozygotic twins could inflate any linkage statistics; programs such as Graphical Relationship Representation (Abecasis *et al*., 2001) can be used to locate incorrect family relationships by a scatter plot of the mean against the variance of the number of alleles identity-by-state for the typed markers for all pairs of individuals in the sample. Programs such as PREST and ALTERTEST (Sun *et al*., 2002), which perform multiple tests of a number of possible relationships, can also be used to assess family relationships in linkage samples. Genotyping errors can be checked for by searching for Mendelian incompatibilities (e.g., with the program PEDSTATS) and double recombinants, which are indicative of unlikely genotypes. Genotyping error rates are typically 1% or less.

2.3. Statistical analysis

Many programs are available for complex disease linkage analysis (**http://linkage.rockefeller.edu/soft/**) and can be used for categorical or quantitative traits. Programs such as GeneHunter (Kruglyak *et al*., 1996) or Merlin (Abecasis *et al*., 2002) take a collection of categorical (GeneHunter) or quantitative (GeneHunter or Merlin) trait and genetic marker values, a pedigree, and a marker map. This data is used to perform single-point and multipoint linkage analyses of pedigree data, including parametric, identity by descent (IBD), and nonparametric and variance component linkage analyses. The general output generated is a plot of QTL (quantitative trait loci) location versus LOD score (for parametric analysis) or Z-score (for nonparametric analysis).

Levels of significance can be denoted as a genome-wide p-value, that is, the probability that the observed value will be exceeded anywhere in the genome, assuming the null hypothesis of no linkage. Criteria for linkage in complex disease are a little different from those for single-gene traits (Lander and Kruglyak, 1995; Sawcer *et al*., 1997), with an LOD score of about 3.3 being regarded as significant evidence of linkage. Lower LOD scores may still represent true positives, and an LOD score of 2 can be regarded as suggestive linkage. Linkage has been regarded as confirmed when a significant linkage observed in one study is confirmed by finding an LOD score or p-value that would be expected to occur 0.01 times by chance in a specific search of the candidate region. However, meta-analysis of linkage data is a more powerful approach for complex disease linkage analysis.

2.4. Meta-analysis

Linkage approaches have been partially successful for complex diseases, and a large body of linkage data has been built up for most complex phenotypes.

In schizophrenia for example, there have been at least 20 genome-wide scans (Lewis *et al*., 2003), and for BMI more than 30 (Obesity gene map database; **http://obesitygene.pbrc.edu/**), and these have led to the putative identification of genetic loci identified in more than one study. However, although statistically significant findings have sometimes been supported by subsequent studies, there is a general lack of consistency for most phenotypes in complex disease linkage analysis. Indeed, some genome scans fail to find linkage at all (Altmuller *et al*., 2001). This could be because susceptibility is conferred by alleles at combinations of loci, each with a small effect on risk, and that the loci of greatest effect vary considerably in their impact between samples, because of geographic variation. False-positive findings are also likely to have arisen, and this could occur more than once for particular loci given the large number of genome scans (Lander and Kruglyak, 1995).

One major issue with linkage is statistical power. Because susceptibility loci for complex diseases are expected to have a small population-wide effect on susceptibility, it is thus difficult to detect their presence consistently without very large samples. For small genetic effect sizes, genome scans with low statistical power tend to overestimate the effect of loci with the highest scores in the scan, that is, maximize the genetic parameters (Goring *et al*., 2001). Genome scans for complex diseases have typically been underpowered – up to 1000 sibling pairs would be required to reliably demonstrate locus-specific genetic effects causing an approximately 30% increase in risk to siblings (Hauser *et al*., 1996). Multiplicative genetic effects are even more difficult to detect (Rybicki and Elston, 2000).

One way to overcome the issue of power is to perform meta-analyses of genome scans, for which several strategies are available (Xu and Meyers, 1998; Gu *et al*., 2001; Zhang *et al*., 2001; Etzel and Guerra, 2002; Dempfle and Loesgen, 2004). The most robust approach would be to pool the raw data using the original genotypes for each study, construct a combined map of the markers, and perform new linkage analyses, which should find loci consistently (Guerra *et al*., 1999). In practice, this is not easily done as raw genotype data may not be readily available or restricted by commercial confidentiality. In the absence of raw data, combining significance or effect estimates can provide an overall, but more limited, assessment of different linkage studies. Genuine meta-analyses combine statistics from different studies, and can be divided into those that combine significance tests (e.g., p-values from across studies) and those that combine effect estimates and test the significance of the common effects (Dempfle and Loesgen, 2004).

Combining significance tests can be performed using Fisher's method for p-values (Guerra *et al*., 1999), and various modifications are available to combine p-values only below a certain threshold (Zaykin *et al*., 2002; Olkin and Saner, 2001) for avoiding bias when truncated LOD scores are used (Province, 2001; Wu *et al*., 2002), and for correcting for multiple testing on the basis of the size of the region-implicated multiple scan probability (MSP; Badner and Goldin, 1999).

Unlike the above methods, the Genome Scan Meta Analysis method (GSMA; Wise *et al*., 1999; Levinson *et al*., 2003) was specifically designed for meta-analysis of linkage data, and is a nonparametric rank method that relies on combining effect estimates and testing the significance of the common effects. It requires only placing markers within 30-cM bins and the rank ordering of each

bin within and then across studies, allowing the consideration of any linkage test statistic and avoiding the need for the same set of markers to be used. However, GSMA provides no formal test of genetic hetereogeneity, and the interpretation of genome-wide statistical significance currently relies on empirical grounds.

Other nonparametric meta-analyses combine IBD statistics, using the number of alleles common across relative pairs (Gu *et al*., 1998, Gu *et al*., 1999). Sample size can also be accounted for (Goldstein *et al*., 1999). Methods for pooling of quantitative trait data are also available (Zhang *et al*., 2001), such as combining Haseman–Elston regression coefficients in a random effects model (Etzel and Guerra, 2002).

2.5. QTL mapping complex phenotypes in the mouse

Genetic mapping of complex traits in animals is attractive because of the statistical power and simplicity of the genetics (Flint and Mott, 2001). Linkage analysis of a complex trait in a cross between two inbred strains of mice relies on the fact that there are only three genotypes at a given locus since the parents are homozygous, meaning that, in effect, a test of association is being performed. This is more powerful than the tests of linkage across human families as the variance has a common basis across all the animals tested, and sources of variance as low as 5% can be detected.

Mouse genetic models for complex diseases are very powerful when used for the mapping of QTLs, such as anxiety, hypertension, and adiposity (Abiola *et al*., 2003). Typically, two inbred strains are crossed to form the F1 progeny, which are then intercrossed to generate an F2 generation or backcrossed to one of the parental strains. Since each progeny chromosome has undergone one meiosis, it will contain about one recombinant per morgan on average, meaning only 3–4 markers per chromosome need be typed for mapping. The genotype at any locus in the F2 must be homozygous for either parental allele, or heterozygous. For each marker locus, the trait mean is examined for each grouped genotype from the F2 progeny, and tested for statistically significant difference. Markers close to a QTL have similar genotypes to those at the undetected QTL and, consequently, the test at such a marker will be almost equivalent to testing for differences at the QTL.

Using various breeding designs (Silver, 1999), such as F2 crosses, recombinant inbred strains (Plomin *et al*., 1991; Williams *et al*., 2001), congenic strains, and chromosome substitution strains (Nadeau *et al*., 2000; Singer *et al*., 2004), more than 100 QTL loci in mice have been detected, reflecting the large-scale simple genetic structure of QTL genetic effects (Flint and Mott, 2001). In theory, under such a simple architecture, fine-mapping in order to identify the underlying genetic variants should be possible, using large numbers of mice to generate recombinants around the QTL, despite the fact that the effect of each (∼5% of the variance) is weak. However, from these 100+ mouse QTLs, only one actual gene underlying a QTL effect has been isolated (Yalcin *et al*., 2004), and in plants, only genes for moderate to major QTLs have been identified despite the use of thousands of crosses for mapping. The reason for this is the hidden complexity of QTLs; each locus detectable by mapping may not map to a single gene, but a group of QTL “increaser” and “decreaser” alleles that lie within a cluster of genes covering a

large (up to 30 cM) region (Darvasi and Soller, 1997; Legare *et al*., 2000; Flint and Mott, 2001). Furthermore, loci can interact synergistically (epistasis), an effect that cannot easily be detected by QTL methods. As a result of these factors, methods such as recombination mapping and the use of congenic strains may fail to identify the underlying QTL.

Methods to overcome this have focused on intermating strategies to break down linkage and increase mapping resolution, particularly those that use outbred stocks of mice to create advanced intercrosses (Talbot *et al*., 1999; Mott *et al*., 2000). Thus, a mapping resolution for a QTL of less than 1 cM has been achieved with genetically heterogeneous HS mice, for which each chromosome is a fine-grained mosaic of the eight founder chromosomes that make up the stock.

With the optimum approach, it is possible to perform fine-mapping to identify at least a group of candidate genes; however, the final problem is the identification of which gene harbors the QTL. Mapping studies are aimed at identifying DNA polymorphisms that alter the trait of interest, and a functional polymorphism can lie anywhere within or near a gene; for example, enhancers tens of kilobases away from the coding part of a gene are known, so the location of the QTL allele may not necessarily implicate a particular gene. Furthermore, there may be hundreds of neutral polymorphisms within the region of interest, and it is currently difficult and laborious to use bioinformatic and functional genomic analysis to tell which is a QTL allele and which is not. However, methods such as transgene complementation can help identify which gene is involved, if not which polymorphism (Flint and Mott, 2001; De Luca *et al*., 2003; Yalcin *et al*., 2004).

3. Fine-mapping in humans

While it has been possible to map genes that have a large phenotypic effect and can thus be localized by the use of recombinants, the reduced penetrance in complex diseases means that recombination events cannot be used to reliably map the position of susceptibility alleles. Statistical approaches based on analysis of recombinants are also not reliable because of the small numbers that occur within each family. Thus, in almost all cases, it has not proved possible to identify complex disease genes by linkage mapping alone.

After the initial genome scan, a linked region will typically be refined with additional microsatellite markers to drain the region of any residual informativeness for linkage. Although this may increase the LOD score of the region, it may only sharpen the linkage peak a little. Further efforts at refining linkage peaks, such as ordered subset analysis, may be used (Hauser *et al*., 2004). However, linkage will leave a candidate locus of as much as 10 cM, which will contain on average 80 genes.

3.1. Positional candidate genes: a mapping shortcut

If the region is reasonably well defined and the pathophysiology of the disease fairly clear, this may allow the selection of candidate genes based on position and function, which can be directly evaluated for their contribution to the trait under test

by association analysis. While this is a strong approach for diseases with specific tissue or cellular localizations and characteristic pathology, such as eye disease or diabetes, this approach has been less successful for most diseases, including psychiatric diseases such as schizophrenia or depression, where information on pathophysiology is poor.

Many techniques can be used to identify strong candidate genes from within linked regions. These include data mining techniques that take advantage of the increasing level of knowledge on gene function. For example, Perez-Iratxeta *et al*. (2002), Perez *et al*. (2004), and others use systematic annotation of genes with controlled vocabularies to develop a scoring system for the possible functional relationships of human genes to genetically inherited diseases, including complex diseases. The Gene Ontology Annotation (GOA) database (**http://www.ebi.ac.uk/GOA**) (Camon *et al*., 2004) provides high-quality electronic and manual annotations to the UniProt Knowledgebase (Swiss-Prot, TrEMBL, and PIR-PSD) using the standardized vocabulary of the Gene Ontology (GO; *see* Article 82, **The Gene Ontology project**, Volume 8), allowing functional assessment of many genes. The goal of the GO project is to produce a controlled vocabulary that can be applied to all organisms even as knowledge of gene and protein roles in cells is accumulating and changing (Ashburner *et al*., 2000; Lewis, 2005).

Other methods can also be used in the gene identification process, such as transcriptomics (reviewed in Farrall, 2004) and proteomics (Jaffe *et al*., 2004; *see also* Article 94, **Expression and localization of proteins in mammalian cells**, Volume 4); in disease mapping, these approaches can annotate gene databases with useful functional information and can be used to attempt to identify changes in protein or mRNA levels, distribution or function that can be used to implicate genes in the disease process. These approaches are largely unproven at present, as many of these changes can be secondary to the disease process or confounded by factors such as medication.

4. Positional cloning by linkage disequilibrium: fine-mapping

Fine-mapping strategies focus on systematically searching for genetic markers from within a linkage locus that are associated with the disease or trait in question, and can also be applied to genome-wide analysis (see below). In the human genome, there are more than 6 million common (minor allele >0.1) SNPs in about 3.2 billion bp (Kruglyak and Nickerson, 2001), plus more than 500 000 VNTRs (variable number of tandem repeats). This translates to about 1 SNP every 500 and 1 VNTR every 6000 or so base pairs, equivalent to tens of thousands of potential disease-susceptibility polymorphisms in any complex disease linkage locus.

This high density of markers provides a problem for fine-mapping studies, as there are a large number of potential susceptibility alleles within any given locus. However, the existence of linkage disequilibrium (LD; also known as allelic association) means that these markers are not independent of each other, and it is possible to infer the location of a disease-susceptibility allele without actually genotyping it (Weiss and Clark, 2002; *see also* Article 17, **Linkage disequilibrium and whole-genome association studies**, Volume 3). Thus, if a particular genetic marker is in

LD with a disease or trait susceptibility allele, the marker will also be in LD with the disease or trait. LD in the human genome, at least in non-African populations, is higher than what had been expected, making the LD approach highly promising for mapping studies. However, intervals displaying association may be relatively wide and hence contain many genes, especially in admixed or isolated populations, a finding borne out by the analysis of QTLs in the mouse (Flint and Mott, 2001).

LD is present when recombination between alleles is rare, because they are physically close together on the same chromosome. Thus, instead of the alleles of two adjacent markers being randomly distributed with respect to each other, as they would be if they occurred on separate chromosomes (or indeed far apart on the same chromosome), their distribution becomes nonrandom and the alleles exhibit LD. This also means that there are a limited number of haplotypes in any given region, reducing genetic complexity (Boehnke, 2000).

4.1. Measurement of LD

LD is an unpredictable measure; unlike linkage, which is hierarchical, physical or genetic distance cannot be used to predict LD between markers. Markers only a few hundred base pairs apart may be in weak LD, whereas markers separated by hundreds of kilobases may be in very strong LD. Consequently, LD must be measured experimentally.

Measurements of LD typically capture the strength of association between pairs of biallelic sites (pairwise LD), and are usually measured using the statistics D' (Lewontin, 1964) or R^2 (sometimes denoted $\Delta 2$; Devlin and Risch, 1995) (see Wall and Pritchard, 2003 for review). Both are normalized statistics, that is, they measure the range from 0 (no LD) to 1 (complete LD), but their interpretation is different. D' is defined as equal to 1 if just two or three of the possible four haplotypes of a pair of biallelic markers are present. Intermediate values of D', where all four haplotypes are present, are variable and difficult to interpret (Hudson, 1985; Hudson, 2001; Pritchard and Przeworski, 2001). In contrast, the R^2 metric only reaches 1 if only two of the four haplotypes are present, that is, each allele is completely associated with just one other. It has a simpler inverse relationship with the sample size required to detect association with susceptibility loci. Thus, to detect a susceptibility allele using a nearby genetic marker in LD with it, the sample size needs to be increased by a factor of $1/R^2$ in comparison to examining the susceptibility polymorphism directly.

Other measures that examine LD across regions rather than just pairwise are possible, such as the measure ρ measures how much recombination would be required under a particular population model to generate the observed LD (Wall and Pritchard, 2003). Metric maps of LD in the human genome are also being created (Maniatis *et al*., 2002; Tapper *et al*., 2003) on the basis of LD units rather than positions in kilobases.

4.2. Fine-mapping strategies: subjects

Families used for linkage analysis are not likely to have sufficient power for fine mapping based on LD, and most investigators will collect a population sample of

cases and controls, or nuclear families, for the mapping process (*see* Article 51, **Choices in gene mapping: populations and family structures**, Volume 1 and Article 60, **Population selection in complex disease gene mapping**, Volume 2). There has been considerable debate on which are the most effective study samples for complex gene-mapping efforts (*see* Article 51, **Choices in gene mapping: populations and family structures**, Volume 1 and Article 60, **Population selection in complex disease gene mapping**, Volume 2).

Unrelated individuals have most often been used for LD mapping and association studies, mainly because of the simplicity of design and the ease of collecting samples, and the advantages of family-based analysis are in general not thought to be substantial (Morton and Collins, 1998). The main consideration for case–control association studies is population stratification (*see* Article 75, **Avoiding stratification in association studies**, Volume 4), as allele frequencies vary substantially between different human populations (a population is defined as stratified if it consists of more than two ethnic groups each with differing population allele frequencies). In effect, this results in poor case–control matching and false-positive (or sometimes false-negative) association results.

Using individual-specific inferred haplotypes as covariates in standard epidemiologic analyses (e.g., conditional logistic regression) is an attractive analysis strategy, as it allows adjustment for nongenetic covariates, provides haplotype-specific tests of association, and can estimate haplotype and haplotype × environment interaction effects (Kraft *et al*., 2005). Several methods, including the most likely haplotype assignment and the expectation substitution approach (Schaid, 2004; Zaykin *et al*., 2002; Stram *et al*., 2003) are available.

A variety of methods for the use of genomic controls to avoid stratification bias has been proposed (*see* Article 75, **Avoiding stratification in association studies**, Volume 4), which can detect and control for population stratification in genetic case–control studies (Devlin and Roeder, 1999; Devlin *et al*., 2001; Reich and Goldstein, 2001). A combined approach of careful ethnic assessment of study populations, because of the strong correspondence between genetic structure and self-reported race/ethnicity categories (Tang *et al*., 2005) combined with genomic control approaches may be the most efficient (Lee, 2004). Genotyping error can be minimized experimentally, for example, by using two different methods for genotyping the same sample; and using samples such as duplicates and identical twins to measure error rates. While this will increase costs, there may be significant enhancement in the ability to detect association, especially when the number and complexity of haplotypes is high (Kirk and Cardon, 2002).

Family-based association studies, such as the case-parents and the case-sibling designs (Risch and Merikangas, 1996), gained popularity for disease mapping since they avoid the problems of case–control matching though making marker comparisons are between members of the same family (Ewens and Spielman, 1995). However, theoretical and empirical study on the degree of population stratification bias in non-Hispanic European populations found the bias to be minimal (Wacholder *et al*., 2000). The use of nuclear families in association does not offer great advantages over case–control analysis for the detection of genotyping errors, particularly as there is no inheritance test for the nontransmitted alleles used as controls in family-based analysis. However, since phase information is available,

family-based haplotype tests may be particularly useful in mapping studies (Lange and Boehnke, 2004; Lin *et al*., 2004).

Certain populations may have advantages for genetic mapping; for example, LD intervals reach up to 1 Mb in general alleles of young subisolates, which may provide advantages for the initial locus positioning of complex traits (Varilo and Peltonen, 2004). Observations on LD parameters indicate that Eurasian populations (especially isolates with numerous cases) are efficient for genome scans, and populations of recent African origin (such as African-Americans) are efficient for identification of causal polymorphisms within a candidate sequence, since LD is lower (Lonjou *et al*., 2003). The main disadvantage of small isolates is statistical power; it may not be possible to obtain a large enough population for mapping studies and for the same reason opportunities for replication in the same population may be limited.

4.3. Fine-mapping strategies

Attempts to localize complex disease-susceptibility genes have focused on methods aimed at detecting LD between individual genetic markers, their haplotypes, and putative disease-susceptibility loci, and is already in use in complex disorders. The first applications were to major loci that could be assigned to haplotypes by family study (Kerem *et al*., 1989; Devlin and Risch, 1995; Terwilliger, 1995). These and other studies have provided the foundation for the application of LD mapping for positional cloning of common diseases in complex inheritance. A 10-cM region displaying linkage with a disease will contain about 20 000 SNPs, assuming its physical size is 10 megabases. To fine-map a 10-cM linked region with individual SNPs, about 3000 individual markers would be required, based on calculations used to estimate the number of SNPs required for a whole-genome scan (Carlson *et al*., 2003).

4.4. Mapping using haplotypes

Historically, association tests were limited to single variants, so that the allele was considered the basic unit for association testing. However, the use of haplotypes, or haploid genotypes, has become increasingly popular (*see* Article 12, **Haplotype mapping**, Volume 3). Many haplotype analysis methods require phase (i.e., family transmission) information inferred from genotype data. However, as the number of loci increases, the information loss due to haplotype ambiguity increases rapidly (Hoh and Hodge, 2000). Several strategies involving the expectation-maximization (EM) algorithm (Ott, 1977; Slatkin and Excoffier, 1996) have been proposed to overcome the problem of missing phase information for estimating haplotype frequencies (Excoffier and Slatkin, 1998; Hawley and Kidd, 1995; Chiano and Clayton, 1998). In general, EM estimation of haplotype frequencies for multiple genotypes is a better strategy for the recruitment of family members or intensive laboratory haplotyping for haplotype-based genetic studies. The availability of population-based haplotype databases will simplify this process further. However,

for most methods it is necessary either to discard families with ambiguous haplotypes or analyze the markers separately, resulting in potential loss of power (Cheng *et al*., 2003). For haplotype analysis, a frequency threshold for the inclusion of haplotypes (usually >3%) can be set to protect against misleading results due to rare alleles or haplotypes.

Methods for haplotype analysis of regions have focused on moving window analysis, in which a scan of sets of tightly linked SNPs is made across the region of interest, in order to identify the site of LD with the trait under test. This can require assigning a window width first and then analyzing multisite parental transmission data under this fixed width (Clayton, 1999; Zhao *et al*., 2000). Other procedures that can maximize LD with an appropriate window width of haplotype transmission data within a preset range have also been proposed (Cheng *et al*., 2003).

The analysis of LD in the human genome has led to the proposed use of haplotype-map-based LD approaches to mapping genes (Cardon and Abecasis, 2003; Wall and Pritchard, 2003). This arose from the observation that LD in the human genome appears to consist of "haplotype blocks", stretches of DNA where strong LD exists between markers, punctuated by areas of weak LD where recombination rates are much higher (Jeffreys *et al*., 2001; Daly *et al*., 2001; Patil *et al*., 2001). These blocks extend for <10 to more than 100 Kb, and have low haplotype diversity, meaning that, in theory, relatively few SNPs could be used to describe the haplotypes of a given region. Haplotype tagging is potentially an efficient way of mapping linkage loci, since it should be possible to use a small set of "htSNPs" to analyze each block in a linked region, reducing the effort by 75% or more (Johnson *et al*., 2001; Patil *et al*., 2001).

Under this model, mapping a linked locus of 10–20 cM would involve dividing the region into 100–200 blocks for analysis, each of which is tagged by a finite number of htSNPs (perhaps 5–10). Thus, a single large region could be fine-mapped by 500–1000 htSNPs. Various methods have been proposed for the selection of htSNPs (reviewed in Lin and Altman, 2004), including manual selection for small genomic regions (Daly *et al*., 2001; Johnson *et al*., 2001), systematic evaluation of subsets with a metric to evaluate each candidate set (Patil *et al*., 2001), analysis of all pairwise comparisons to select the htSNPs explaining the most haplotype diversity (Daly *et al*., 2001), entropy (Judson *et al*., 2002; Avi-Itzhak *et al*., 2003; Hampe *et al*., 2003), or minimization of the squared correlation between the estimated and the true number of copies of haplotypes (Chapman *et al*., 2003; Stram *et al*., 2003). Alternative approaches, which measure how well individual and sets of SNPs predict one another (Bafna *et al*., 2003), are based on set theory and recursive searches for the minimal set of SNPs from which the maximum number of the other SNPs in the data set can be derived (Sebastiani *et al*., 2003), or clustering SNPs by pairwise LD measures and then selecting one htSNP per cluster (Carlson *et al*., 2004). More recently, principal component analysis (PCA) has been proposed as an efficient method, and evidence suggests that it tends to select the smallest set of htSNPs to achieve a 90% reconstruction precision (Meng *et al*., 2003; Lin and Altman, 2004).

While good computational methods are available for efficient analysis of haplotype blocks, it is not yet clear how well defined they are in real populations and whether they are stable across diverse ethnic groups (van den Oord and

Neale, 2004). Some studies indicate that haplotype blocks are stable across diverse populations (Gabriel *et al*., 2002; Dawson *et al*., 2002), which would allow the generation of general human LD maps, analogous to the recombination maps created for linkage analysis (Maniatis *et al*., 2002). However, this model of the LD structure of the human genome may be excessively simplistic. For example, there is evidence that much of the genome may not be formed into haplotype blocks (Phillips *et al*., 2003), and that where blocks exist they are not necessarily discreet entities because of long range LD (Daly *et al*., 2001; Jeffreys *et al*., 2001; van den Oord and Neale, 2004).

The remaining challenge is then to refine the techniques for fine-mapping of the causal polymorphism(s) within regions of high LD. Obviously, if strong blocks exist, then it will require a combination of genetic and molecular biological methods to identify which of the SNPs within the block are causal. Methods based on single marker tests within a composite likelihood framework (Maniatis *et al*., 2005) can apply a model with evolutionary theory that incorporates a parameter for the location of the causal polymorphism.

4.5. Positional cloning by linkage disequilibrium – genome-wide approaches

The success of linkage analysis in identifying genes for single-gene disorders reflects the fact that it has substantial power to identify rare high-risk disease alleles, since IBD allele sharing for this type of genetic risk factor will be very high between affected individuals in pedigrees. However, for modest risk alleles, such as those operating in complex disorders, allele sharing between affected subjects will be much less evident (Carlson *et al*., 2004); for example, it has been estimated that samples of 600–1000 affected sibling pairs would be required to reliably demonstrate locus-specific genetic effects causing a 27–30% population-wide increase in risk to siblings (Hauser *et al*., 1996); typical sample sizes for complex disease linkage analysis are in the low hundreds.

Consequently, the most accepted route to mapping complex disease genes, linkage followed by LD mapping or positional candidate gene analysis, may miss loci that have modest effects on risk unless very large sample sizes or meta-analyses are employed. Association analysis, at least theoretically, has more power to detect common disease alleles that confer modest risk (Risch and Merikangas, 1996). It is also easier to attain high statistical power as larger numbers of case–control or family trio samples are available than multiply affected families, which can be elusive. However, because there are many more generations from the most recent common ancestor in an association sample, much higher marker densities are needed to detect association compared to linkage (Kruglyak, 1999; Gabriel *et al*., 2002).

Thus, whole-genome association has been proposed as an alternative approach to linkage followed by fine-mapping (*see* Article 17, **Linkage disequilibrium and whole-genome association studies**, Volume 3), in which a dense genome-wide set of SNPs is tested for disease association under the assumption that if a risk polymorphism exists, it will either be genotyped directly or be in strong LD with

one of the genotyped SNPs. This is essentially a single-point approach, where markers are analyzed one by one, but other approaches such as "moving window" haplotype analysis or multipoint haplotype analysis are also possible (Morris *et al*., 2003). Family samples can also be used for genome-wide analysis. Lin *et al*. (2004) describe an algorithm and a statistical method that efficiently and exhaustively exploits haplotype information from sliding windows of all sizes to transmission disequilibrium tests, which can detect both common and rare disease variants of small effect.

Estimates of the number of SNPs required for whole-genome association vary, but a requirement for between 300 000 and 1.3 million SNPs has been suggested on the basis that strong LD operates over short distances, and empirical analysis of specific region (Kruglyak, 1999; Gabriel *et al*., 2002; Carlson *et al*., 2003). Both direct (gene-based) and indirect (neutral marker) mapping approaches have been suggested. In the indirect approach, a dense set of neutral SNPs is used in the hope of detecting LD with causative SNPs, whereas in the direct approach, each of the 25 000 or so human genes would be analyzed by a set of representative SNPs in each gene, with an attempt to focus on potentially functional SNPs (Kruglyak, 1999; Botstein and Risch, 2003; Neale and Sham, 2004). A focus on analyzing SNPs that alter coding regions (cSNPs) has been proposed, and there is some evidence that some complex disease causing polymorphisms will be cSNPs; however, it is at least as likely that complex disease risk alleles will lie in noncoding regulatory regions of genes, as seen for nonhuman QTLs (Yalcin *et al*., 2004; Flint and Mott, 2001) such as promoters, where it is difficult and laborious to assess the functionality (Buckland *et al*., 2004).

Neale and Sham (2004) have proposed a shift toward a gene-based approach in which all common variants within a gene are considered jointly, thus capturing all potential susceptibility alleles. This has advantages for the consideration of genetic differences in population, which are more readily resolved by use of a gene-based approach rather than either a neutral SNP-based or a haplotype-based approach. Thus, negative findings are subject only to the issue of power. Once all gene variants are characterized, the gene-based approach may become the natural end point for association analysis and will inform our search for functional variants relevant to disease aetiology.

Whole-genome approaches are dependent on assembling an adequate SNP marker map, for which difficulty in selecting SNPs comes principally from ethnic variation in LD and in SNP frequency. Carlson *et al*. (2003) estimate that even analyzing all 2.6 million SNPs known in 2003, only 80% of all common SNPs in European and 50% in African-origin populations would be detected; as many as a quarter of all SNPs seen in African populations are "private", that is, they do not exist elsewhere, meaning that SNP marker maps may need to be population specific and very dense. Improvements in efficiency may be achieved by forming SNPs into haplotypes and haplotype blocks that can be tagged with htSNPS, as proposed for locus-specific fine-mapping. However, this will require the completion of the human haplotype map (The International HapMap Consortium, 2003).

Microsatellite markers have also been proposed for whole-genome association. Ohashi and Tokunaga (2003) calculated a markedly higher power for microsatellite markers than for SNPs, even if more SNPs are analyzed, suggesting that the use of

microsatellite markers is preferable to the use of SNPs for genome-wide screening under certain assumptions. This method will be helpful for researchers who design genome-wide LD testing with microsatellite markers.

DNA pooling (Barcellos *et al*., 1997) has been proposed as a method to economize on the number of genotypes required for whole-genome association studies. Pooled genotyping is a powerful and efficient tool for high-throughput association analysis, both case–control and family-based. The use of pooling designs can significantly reduce the costs of a study. At the same time, since it is also extremely efficient with DNA resources, pooling can be an extremely effective method for conserving DNA (Sham *et al*., 2002; Norton *et al*., 2004). Sophisticated pooling designs are being developed that can take account of hidden population stratification, confounders, and interactions, and that allow the analysis of haplotypes (Hoh *et al*., 2003). Both microsatellites (Daniels *et al*., 1998; Breen *et al*., 1999) and SNPs (Breen *et al*., 2000) are amenable to the pooling approach. Pooling approaches that allow chip-based genotyping may be particularly cost-efficient and rapid.

Whole-genome analysis also raises the statistical problem of multiple testing and levels of significance when using hundreds of thousands of genetic markers (Carlson *et al*., 2004), requiring substantial Bonferroni correction. There are no obvious methods that can exclude false-positives while capturing true positives for genetic effects that are weak, aside from repeated replication and meta-analysis, which may be subject to bias and are not a substitute for an adequately powered primary study (Munafo and Flint, 2004). It may be possible to overcome this problem using very large samples sizes (e.g., 2000 cases and 2000 controls), and practical methods have been proposed to help identify important genetic factors more efficiently, such as ranking markers by proximity to candidate genes or by expected functional consequence. Single marker tests within a composite likelihood framework have also been proposed, and will avoid heavy Bonferroni correction (Maniatis *et al*., 2005).

Specialist Review

Haplotype mapping

Alexandre Montpetit, Fanny Chagnon and Thomas J. Hudson

McGill University and Genome Quebec Innovation Centre, Montreal, QC, Canada

1. Introduction: linkage, association, and linkage disequilibrium (LD) mapping

Linkage mapping is based on coinheritance of large chromosomal stretches among members of a family sharing a common phenotype. This approach has been very successful for rare Mendelian diseases, but it has led to mixed results for common diseases (Lander and Kruglyak, 1995). Many factors, such as low penetrance, small sample size, different diagnostic or disease definitions, and uncertainty in the position of the linkage peak have contributed to the low success of family based genome scans. Association approaches can directly test functional polymorphisms or indirectly test mutations using genetic markers in linkage disequilibrium (LD) with the mutation. Association and LD mapping traditionally compare samples of cases and controls, but alternate strategies exist, such as the comparison of transmitted alleles inherited by an affected offspring with the untransmitted alleles of the parents. Association methods have greater power to detect small and moderate genetic effects than linkage analysis and, thus, are more suited for the identification of variants predisposing to common diseases (Risch and Merikangas, 1996). However, it is not currently feasible to perform association scans at the genome scale, and a mixed approach is typically used (see Table 1) (*see also* Article 11, **Mapping complex disease phenotypes**, Volume 3 and Article 17, **Linkage disequilibrium and whole-genome association studies**, Volume 3 for more details on linkage and association mapping of common diseases).

While microsatellites were the markers of choice for linkage studies because they are highly informative, they cannot be used reliably for association studies because of their relatively high mutation rates. Single nucleotide polymorphisms (SNPs) are more stable and more abundant than microsatellite markers, enabling investigators to cover extensively any genomic region (Risch, 2000). There are estimates of 10 to 15 million common SNPs having a minimal minor allele frequency greater than 1% in the human population (Kruglyak and Nickerson, 2001). Using population simulations to estimate LD, Kruglyak (1999) hypothesized that the extent of useful levels of LD for association studies in the general outbred population is about 3 kb, implying that about 500 000 SNPs would be needed for a genome-wide association

Table 1 Examples of haplotype mapping studies

Disease	No. of cases/families (population)	No. of SNPs (density)	Gene/haplotype identified	Region	Haplotype frequency	Replication panel	References	Replication in independent study
Type 2 diabetes	110 cases (Mexican Americans)	114 (1/15 kb)	*CAPN10*	2q37	0.23/0.32	192 cases (Finnish)	Horikawa *et al*. 2000	Meta-analysis of 17 studies (Weedon *et al*., 2003)
Crohn disease	139 trios (Canadian)	301 (1/3.3 kb)	250 kb haplotype in the cytokine cluster	5q31	0.37	88 trios (Quebec)	Rioux *et al*. 2001	368 German trios (Giallourakis *et al*., 2003)

scan. With today's cheapest technology, it would be unfeasible to type them all in a typical case-control study. However, the rate of the LD decay is not uniform throughout the genome. Several studies observed that the local decay in LD is not continuous at all and can sometimes extend for very long distances up to 1-3 cM (Lonjou *et al*., 1999, Mohlke *et al*., 2001, Service *et al*., 2001). LD is known to extend for longer distances in isolated populations (such as populations from Iceland and Finland), or founder populations that experienced a rapid expansion (such as the Amish, or populations from Quebec and Newfoundland), and one might expect that this property should facilitate disease mapping (reviewed in Peltonen, 2000). While the use of isolated or founder populations helped in the identification of single mutations for rare diseases because it reduces allelic heterogeneity, their usefulness for common diseases is still debated (see Kruglyak, 1999).

2. Haplotype blocks

Recent studies using relatively high densities of SNPs enabled the analysis of the LD structure at smaller scales. It was observed that LD decays in sudden discrete drops to form blocklike structures that can extend from a few kilobase pairs to more than 100 kb (Daly *et al*., 2001, Reich *et al*., 2001, Patil *et al*., 2001). Moreover, these blocks seem to have very low diversity, pointing to the fact that most of this diversity comes from a small number of ancestral chromosomes. The specific set of alleles on a chromosomal segment is called a *haplotype*. New haplotypes can arise from new mutations or recombination. Each novel mutation is initially associated with alleles that happened to be present on a particular chromosome on which it arose (thus establishing a novel unique haplotype). These alleles will remain correlated until recombination events occur between them. The existence of recombination hot spots was suggested as an explanation for the presence of these large blocks of low haplotype diversity (or haplotype blocks) (Daly *et al*., 2001). Low haplotype diversity implies that only a few SNPs per haplotype block would need to be typed in order to extrapolate most of the information of the remaining SNPs, which could save considerable time and money.

For example, Rioux *et al*. (2001) applied an LD approach to the investigation of a Crohn disease susceptibility gene linked to chromosome 5q31. In a region spanning 250 kb encompassing several cytokine genes, they observed over one dozen SNPs that are associated with the disease. Daly *et al*. (2001) showed that the region can be subdivided into 11 haplotype blocks, each with only two to four haplotypes describing more than 90% of haplotype diversity at this chromosomal region (Figure 1). Had the underlying block structure been previously known, they could have genotyped as few as 20 SNPs (termed *haplotype tag SNPs or htSNPs*) to test the entire 250 kb. One risk-associated haplotype was identified, but because of the existence of large haplotype blocks and the presence of considerable LD between them, the causative polymorphism (or even the causative gene) cannot be identified using genetic mapping alone. In order to identify which gene or which polymorphism is contributing to the disease, functional studies, such as expression analysis, targeted mutations in vitro, or knockout studies in mice are necessary. Using a different population might also be helpful. Oksenberg *et al*. (2004) used

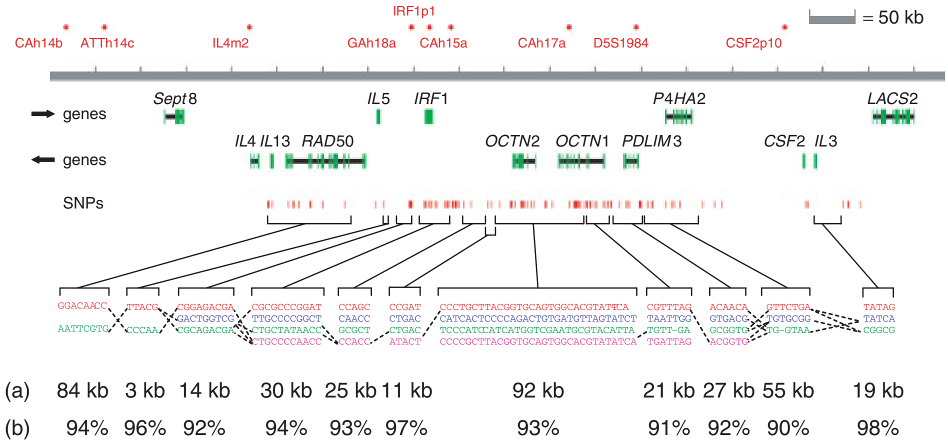

Figure 1 Haplotype structure at the IBD5 locus. (a) Common haplotype patterns in each block of low diversity. Dashed lines indicate locations where more than 2% of all chromosomes are observed to transition from one common haplotype to a different one. (b) Percentage of observed chromosomes that match one of the common patterns exactly. In addition, four markers fell between blocks, which suggests that the recombinational clustering may not take place at a specific base-pair position but rather in small regions. (Reproduced from Daly MJ, Rioux JD, Schaffner SF, Hudson TJ and Lander ES (2001) High-resolution haplotype structure in the human genome. *Nature Genetics*, **29**, 229–232 by permission of Nature Publishing Group)

a cohort of African Americans to define a haplotype in the HLA region that is associated with multiple sclerosis. The African haplotypes in this region do not display the high degree of LD and haplotype structure observed in Caucasians. This enabled the research team to reduce the region to only one gene, *DRB1*, excluding *DQB1*. The fact that many disease-associated SNPs located in the vicinity of one or more genes can be present within a haplotype block, and that LD can be detected across blocks, clearly illustrates the importance of understanding the underlying haplotype structure of a region in the population studied. Using Alzheimer's disease as an example, several studies showed that the association between the ApoE gene and the disease could be identified by using haplotype information even though the true variant was not genotyped (Martin *et al*., 2000, Fallin *et al*., 2001).

Different analytical approaches can be used to construct a comprehensive LD/haplotype map of a selected region. Several methods have been described to identify haplotype blocks and will be explained in more details (*see* Article 74, **Finding and using haplotype blocks in candidate gene association studies**, Volume 4). A color-coded pairwise D' map, constructed with programs such as GOLD (Abecasis and Cookson, 2000), is also very useful to visually examine regions of high and low LD (*see* Article 73, **Creating LD maps of the genome**, Volume 4). Finally, association can be measured using multilocus haplotypes instead of individual SNPs, resulting in an increase in power to detect indirect association and in a decrease in the number of tests performed, thus minimizing the correction applied to the p-value (Zhang *et al*., 2002a). Several studies have successfully mapped an associated gene or haplotype block to a common trait by using a dense set of SNPs to understand the haplotype structure. Some examples are listed in Table 1.

Although recombination hot spots have been observed directly in other species (yeast, *Drosophila*, mouse), it is labor-extensive in humans. Jeffreys *et al*. (2001) used sperm-typing to directly observe meiotic events and infer the existence of recombination hot spots in humans. They observed that 94% of the crossovers occurred at only six positions in the 300 kb HLA region on chromosome 6p. These hotspots for recombination are all between 1 and 2 kb in length. In yeast, hot spots tend to be associated with GC-rich chromosomal regions and form open domains in meiotic chromatin that allow access to the recombination machinery (reviewed in Petes, 2001). However, in humans, no similarity in the primary genomic sequence has yet to be predictive of the hot spots. Recombination hot spots have also been observed in the pseudoautosomal region of chromosome Y (Lien *et al*., 2000, May *et al*., 2002) and in the β-globin gene cluster (Schneider *et al*., 2002, Smith *et al*., 1998). It is still unknown whether these observations are representative of the recombination events in the remaining genome and for all populations. Kauppi *et al*. (2003) showed that although haplotype diversity was different in the HLA region between European and African populations, patterns of LD were similar. We note, however, that the average recombination rate is 1.65 times higher in females than in males, pointing to the fact that mechanisms involved are not homogeneous (Kong *et al*., 2002).

Gabriel *et al*. (2002) extensively genotyped 50 autosomal regions spanning 13 Mb of sequence and found that, on average, haplotype blocks extend for 22 kb in Asian and European populations and 11 kb in the Yoruba population from Nigeria. Using one marker every 7.8 kb, they observed that about 50% of the sequence was in blocks. Using denser sets of SNPs, the fraction of sequence included in blocks will increase but it will be accompanied by a drop in the average block size as additional blocks of smaller size are identified (Ke *et al*., 2004). Gabriel *et al*. (2002) defined blocks as regions in which 95% of the marker pairs show no strong evidence of historical recombination, the latter being based on confidence intervals between D' values. This accounts for some uncertainties, such as finite sample size and unphased diploid data. They observed that block boundaries between populations are extremely similar. This is in agreement with the recombination hot spot theory and it demonstrates that a blocklike model can be applied to the whole genome and to other populations as well. Other studies interpreted similar results differently, explaining that the majority of the blocklike patterns could be explained by population history (Patil *et al*., 2001, Phillips *et al*., 2003). However, the presence of the longest blocks had to be explained by some other mechanism, such as recombination hot spots. Both interpretations, population history and recombination hot spots, clearly play a role in shaping the genome but their relative contribution is still debated today.

Many different definitions of haplotype blocks have been published, and it is known that allelic frequency and SNP density will affect to some degree all block definitions (Zondervan and Cardon, 2004, Ke *et al*., 2004, Schulze *et al*., 2004). Denser genotyping of SNPs will reveal more blocks, shorter in length, while low allelic frequency SNPs will tend to break existing blocks into shorter ones. Also, since recombination does not occur all the time in recombination hot spots (i.e., LD can exist between adjacent blocks and recombination can occur inside blocks), block boundaries will vary between definitions. For these reasons, it is unclear yet

how to compare haplotype blocks between studies or whether the results reflect some underlying biological processes. For a review of the methods to identify and define haplotype blocks, *see* Article 74, **Finding and using haplotype blocks in candidate gene association studies**, Volume 4. Because the Gabriel *et al*. (2002) approach is somewhat more easily understandable to biologists and because it does not need phased haplotype data, it has been more widely used up to now.

3. Building a haplotype map

Following these pilot studies, it became apparent that building a human haplotype map that would describe about 80-90% of the genome that is included in blocks and representing most of the human diversity would be extremely valuable. It was recognized that the existence of such a map would provide a valuable tool to investigators wanting to identify genes involved in common diseases. One would then have to select only a few SNPs in each block in a candidate region without losing much power in an association study (see Figure 2). It is estimated that this map would reduce by 10- to 30-fold the number of SNPs necessary to do any

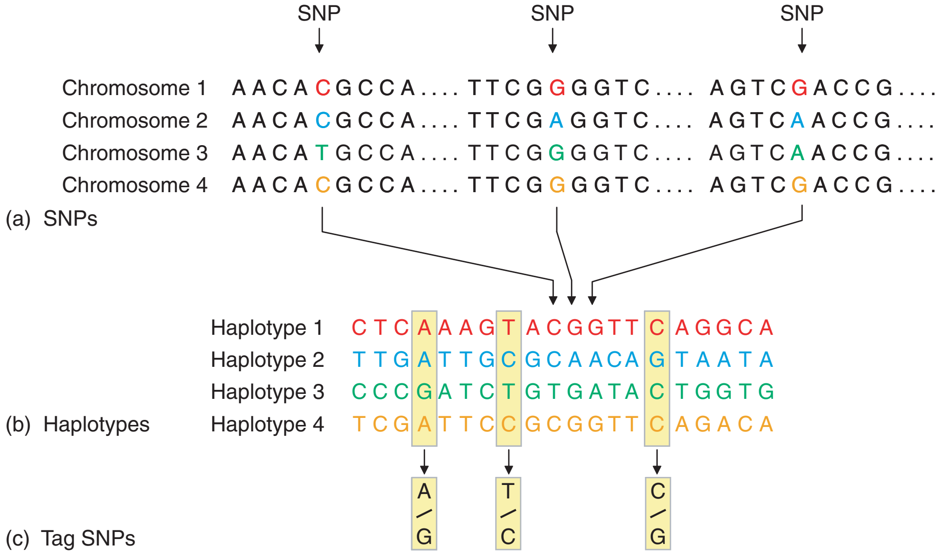

Figure 2 SNPs, haplotypes, and tag SNPs. (a) SNPs. Shown is a short stretch of DNA from four versions of the same chromosome region in different people. Most of the DNA sequence is identical in these chromosomes, but three bases are shown where variation occurs. Each SNP has two possible alleles; the first SNP in panel a has the alleles C and T. (b) Haplotypes. A haplotype is made up of a particular combination of alleles at nearby SNPs. Shown here are the observed genotypes for 20 SNPs that extend across 6000 bases of DNA. Only the variable bases are shown, including the three SNPs that are shown in panel a. For this region, most of the chromosomes in a population survey turn out to have haplotypes 1-4. (c) Tag SNPs. Genotyping just the three tag SNPs out of the 20 SNPs is sufficient to identify these four haplotypes uniquely. For instance, if a particular chromosome has the pattern A-T-C at these three tag SNPs, this pattern matches the pattern determined for haplotype 1. Note that many chromosomes carry the common haplotypes in the population. (Reprinted with permission from Nature, The International HapMap Consortium (2003) The international HapMap project. *Nature*, **426**, 789–796. Copyright 2003 Macmillan Magazines Limited)

association study targeting common risk alleles. For whole-genome association studies, this may involve testing approximately 300 000 to 1 million SNPs, instead of the 10 to 15 million common SNPs in the human genome. The International HapMap Consortium, composed of teams from Canada, the United States, the United Kingdom, Nigeria, China, and Japan, was established in 2002 to build a map that will be useful for association mapping in any human population. Details of the approach were published in the first year of the project (International HapMap Consortium (2003)). As discussed above, although block boundaries are similar between populations of various ancestries, many differences, notably in block length and haplotype frequency, can be observed. Thus, four distinct populations (of European, Chinese, Japanese, and Yoruba ancestry) were initially chosen for their inclusion in the HapMap project. These samples are thought to include a significant amount of the overall human genetic variation and thus, the results should be applicable to most association studies. The human haplotype map should be completed by the end of 2005, but genotypes are made available to all researchers on the web as soon as they are produced. As of May 2004, more than 600 000 SNPs have been genotyped on HapMap samples.

Despite its initial successes, many questions remain unanswered. For example, will the HapMap results be applicable in a different population than those used to create the HapMap? It is known that African subpopulations can exhibit relatively greater differences between each other, as what is usually observed when comparing non-African populations. Likewise, founder populations of Caucasian origin may well present differences in haplotype structure (i.e., length of block) and diversity. It has been shown also that allelic frequency and SNP density can alter, sometimes dramatically, the observed block structure (Zondervan and Cardon, 2004, Ke *et al*., 2004, Schulze *et al*., 2004). The HapMap Consortium elected to use SNPs with a minor allelic frequency of at least 5% in each population used to build the map. This threshold is consistent with those used in the study of common variants causing common diseases (Lander, 1996, Lohmueller *et al*., 2003; *see also* Article 11, **Mapping complex disease phenotypes**, Volume 3). Low frequency variants could still, in principle, be identified using the map, although usually with much lower power to detect them (Zondervan and Cardon, 2004).

It is feasible to produce a haplotype map of a particular locus and/or in a different population. It is necessary to genotype a high-density set of SNPs on a subset of the samples and build a haplotype map that could be used to select tag SNPs to use in subsequent studies in larger cohorts from a population. The first step in building a haplotype map is to define the number of samples needed to build the map. The answer to this question depends on haplotype diversity, but in general, panels of 90 unrelated individuals or 30 trios should be sufficient to detect haplotypes with greater than 5% frequency. Using unrelated samples instead of families can maximize the number of independent chromosomes as many analysis programs can use unrelated samples to accurately determine haplotype phase, including PHASE (Stephens *et al*., 2001), EM method (Excoffier and Slatkin, 1995). However, the use of families can improve the phasing of haplotypes when LD is lower and also provide a measure of genotyping errors (using tests for Mendelian inheritance).

The second step is to select the required density of SNPs. Ke *et al*. (2004) observed that a density of atleast 1 SNP every 2 kb was needed to stabilize the

block boundaries. However, since LD is not homogeneous throughout the genome and because haplotype blocks vary greatly in length, a hierarchical approach was adopted by the International HapMap Consortium (2003). In Phase I of the HapMap project, 1 SNP every 5 kb was genotyped in every population sample to identify large blocks. This 5 kb scan is expected to generate a map with approximately 60% of the genome in blocks. Additional markers are added in regions where LD is too low (i.e., where it is not possible to accurately predict the genotype of a nearby SNP) to cover an additional 20-30% of the genome. This strategy should be valuable for any kind of haplotype map. As of March 2004, there were more than 7 million SNPs in dbSNP, with a large fraction discovered by several resequencing projects of the International HapMap Consortium (2003). More than one million SNPs will be validated by the HapMap project, providing a valuable resource to the human genetics community. It was also shown that using double-hit SNPs (i.e., SNPs independently observed two or more times in SNP discovery projects) improves the overall success rate and correlates with a higher average minor allelic frequency. The third step is to choose the appropriate genotyping platform. Many different platforms exist on the market with wide variation in throughput and price. Highly parallel processing, from a few SNPs to several thousands, has resulted in a reduction of the price per genotype. However, depending on the number of SNPs genotyped, some can be more advantageous than others (*see* Article 77, **Genotyping technology: the present and the future**, Volume 4). The last step is to select a set of tag SNPs that will accurately describe each block in the selected samples and will be used subsequently to genotype the remaining samples (see below).

4. Selecting haplotype tag SNPs

One of the most important contributions of a haplotype map will be the description of a set of haplotype tag SNPs, specific for a population, that will improve significantly the efficiency of subsequent association studies. One straightforward method to pick htSNPs is presented in Figure 2. However, there can be as many htSNP sets as there are haplotype block definitions. Also, even though a blocklike description of the genome sounds appealing, there might be some problems if we rely on them to pick htSNPs: first, there will always be significant LD between adjacent blocks, so a strategy that would try to tag each block, especially very small ones, could be inefficient. Finally, it will be impossible to account for those regions that lie outside a block. Cardon and Abecasis (2003) showed that the best htSNP selection should not be dependent on the concept of blocks but on more general patterns of LD and haplotype diversity. This means that in a selected region, the chosen SNPs must capture the variation that exists at the unexamined sites by LD. Another important variable to consider is the balance between the reduction in the number of SNPs to genotype and the reduction in the power to detect an association.

Zhang *et al*. (2002b) noted that the power is reduced by about 4% when 25% of the total number of SNPs, selected by their method, is used, compared to a drop of 12% when a random SNP set of similar size is chosen instead. When 14% of the SNPs are used, the power drops by 9 and 21%, respectively. Also, power

loss was much greater using single-locus association tests than with a two-locus haplotype approach. Although other published methods seem to perform similarly, the different algorithms do not identify the same number of blocks or htSNPs. For example, Zhang *et al*. (2002a), using the same data as Patil *et al*. (2001), were able to reduce the number of haplotype blocks and htSNPs selected by more than 20%. Various other methods have recently been published that attempt to minimize the number of tag SNPs (Ke and Cardon, 2003, Meng *et al*., 2003, Carlson *et al*., 2004, Schulze *et al*., 2004, Sebastiani *et al*., 2003, Stram *et al*., 2003), pointing to the fact that the optimal way to mathematically define the problem has probably not yet been described or will vary on the basis of local LD in different regions of the genome. Since r^2, a measure of LD, is inversely proportional to the increase in the sample size required to detect an indirect association, the most useful approach, with the knowledge of the Haplotype Map, would be to pick the minimal set of htSNPs that describe all other markers using a r^2 threshold (ex:0.8). This allows the sample size needed to detect the association to be easily calculated (Carlson *et al*., 2003).

In the past decade, significant progress was made in defining the genetic basis of common diseases as well as in genotyping technologies and statistical methodologies. However, the mapping of common disease genes is still an arduous task today. The understanding of the haplotype structure of human chromosomes is crucial to improve the success of association studies. With results from the HapMap project available to all researchers, many studies that previously would have been done with a few nonvalidated SNPs can now be attempted with sufficient power to effectively screen hundreds of candidate genes and large chromosomal regions. It is important to realize that the haplotype mapping approaches are still in their infancy and need to be improved for the full potential of the Human Haplotype Map to be achieved: (1) genotyping costs need to decrease; (2) analysis methods must improve; and (3) pilot studies must evaluate the effect of using different populations or the impact of disease polymorphisms, with various penetrance and allelic frequency, on the success of association mapping of common traits. Despite the caveats, the Haplotype Map will be a powerful tool to systematically screen the genome and elucidate the genetic causes of common genetic diseases.

Specialist Review

YAC-STS content mapping

Claudia Gosele, Heike Zimdahl and Norbert Hubner
Max-Delbruck-Center for Molecular Medicine, Berlin, Germany

1. STS marker

Sequence tagged site (STS) markers represent short unique DNA sequences for which a specific PCR (polymerase chain reaction) assay can be designed, so that any DNA sample can be easily tested for the presence or absence of this specific DNA fragment. One of the hallmarks of an STS is that it maps to a single location in the genome. STSs were proposed as a "common language for physical mapping" (Olson *et al*., 1989), and have emerged as principal markers used in a variety of mammalian maps (*see* Article 9, **Genome mapping overview**, Volume 3). The principle of STS mapping is to create clone maps based on STS content, allowing the correlation between different maps.

A YAC (yeast artificial chromosome)-based STS content mapping approach was first used to construct a map of human chromosome 7 (Green *et al*., 1991) in 1991. The proposed strategy was based on the mapping of large segments of human DNA using YACs as the source of cloned DNA and STSs as landmarks to order these clones and anchor them with radiation hybrid maps. The principle disadvantage of any STS marker approach – compared to hybridization-based markers – lies in the cost of acquiring single-copy sequences and synthesizing oligonucleotides specific to each STS.

2. STS marker development

PCR-based STS content mapping is a highly robust and straightforward technique. It can be applied to all kinds of cloning systems and mapping panels. The scale of STS development can vary from creating a single STS corresponding to an interesting gene sequence for the purpose of locating the gene in the genome, to creating a large number of STSs from a particular chromosome or subchromosomal region as part of a physical mapping project.

Regardless of the origin of STSs or scale of a project, the major steps of STS development are:

1. acquisition of sequence
2. assessment of sequence by comparison of databases

3. selection of PCR primers
4. development of a PCR assay
5. assessment of the uniqueness of an STS by limited mapping
6. assessment of STS quality.

Many genomes contain abundant repetitive sequences, including interspersed repetitive repeats, satellite sequences, and gene families that should be avoided in the development of an STS. Sequences can be compared to databases of known repeat sequences, for example, by using the web-accessible program RepeatMasker (Smit *et al*., 1996–2004).

The primer design should be done on unique sequences. Several algorithms are available for selecting oligonucleotides for PCR (e.g., PRIMER, OLIGO). PCR products that are used to detect an STS are usually 100–1000 bp size, with an average size of approximately 200 bp. If multiplex PCR is used to score multiple STSs simultaneously, a range of product sizes should be selected to facilitate resolution of products from the reaction mixture.

When primers are selected from a cDNA sequence, it is important to select oligonucleotides that are likely to lie within a single exon, to ensure that genomic DNA can serve as a template for the amplification of the STS. Since PCR-based STS content mapping demands a primer design and an oligonucleotide for each marker studied, the costs of a project are increased. Furthermore, PCR has to be done on every clone of a library, followed by the detection of products, which results in a large number of reactions. For screening whole libraries, the collection of clones in pools can circumvent this problem and reduces drastically the number of PCR reactions to be done (see Figure 1).

The next step in STS generation includes the development of a robust PCR assay that can be carried out under standardized reaction conditions. A robust and standardized assay is especially important for projects that involve the generation of more than a small number of STSs because a large number of PCR assays will be carried out.

As an alternative to PCR, genomic libraries can be spotted on high-density gridded filters and several thousands of clones can be screened in a single hybridization step (see Section 4.2).

3. Large-insert clone libraries

With the availability of one or more closely linked DNA markers from a genomic region of interest, one can begin to develop a contig of overlapping clones that spans the region. A cloned contig not only provides information on physical distances but can also be used as the raw material from which positional cloning of a phenotypically defined locus can proceed. The generation of a contig is pursued most efficiently by screening a large-insert genomic library. Although a number of systems for generating large-insert libraries have been described, to date, bacterial artificial chromosomes (BAC) and YAC cloning systems have been used most widely.

The development of YAC cloning technology, first implemented by David Burke and Maynard Olson at Washington University in St. Louis (Burke *et al*., 1987), has

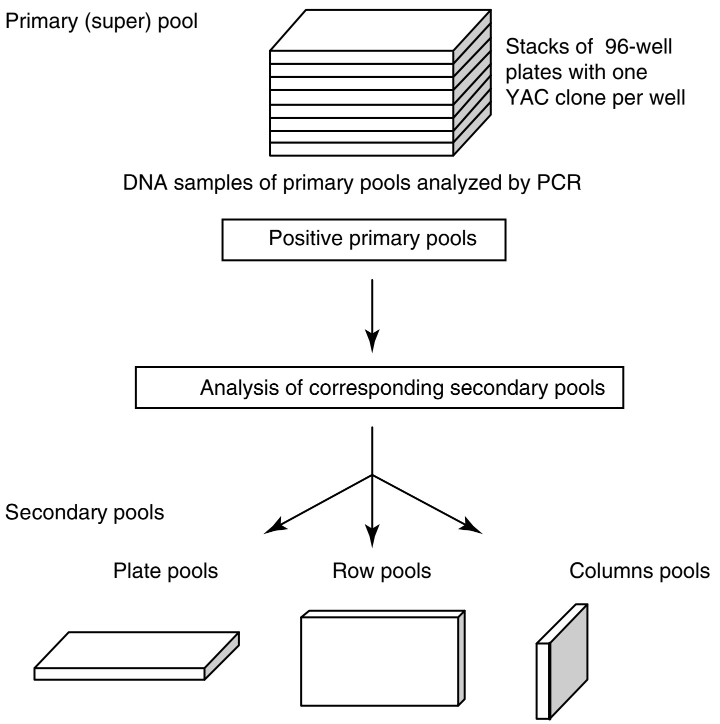

Figure 1 Three-dimensional pooling of clone libraries: A YAC library is usually stored in 96-well plates: one stack consists of 8 plate pools, 8 row pools, and 12 column pools, and PAC/BAC libraries are stored in 384-well plates: one stack consists of 8 plate pools, 16 row pools, and 24 column pools. By pooling clone libraries, the number of PCRs for the library screening is significantly reduced

enabled the cloning of very large fragments of exogenous DNA that range in size up to 2 Mb and thus directly enhanced the relationship between genetic, physical, and functional mapping of genomes. YAC cloning systems are based on yeast plasmids, containing DNA sequences that function as telomeres (TEL), as well as containing yeast origin of replication (ARS) and centromere segments (CEN). "Artificial" yeast chromosomes are formed by ligation of random, large fragments of genomic DNA between two arms that contain, in one case, a telomere and a centromere, and in the other case, a telomere alone, with selectable drug-resistance markers on both arms. These YAC constructs are transfected back into yeast where they will move alongside host chromosomes into both daughter cells at each mitotic division.

The construction of a YAC library proceeds in a manner that is very different from that of most other types of genomic libraries. Every clone in the library must be picked individually and placed into a separate compartment (e.g., of a microtiter dish). This process is extremely time consuming and labor intensive, but once a library has been formed with individual clones in individual wells, it is essentially immortal. For this reason and others, it makes good sense to screen established libraries for a gene of interest rather than to create a new library.

The first human YAC library to be described had a 2.2-fold genomic coverage and an average insert size of ∼265 kb, and was distributed freely to the entire scientific community (Burke *et al*., 1987).

Although YAC clones have facilitated the construction of long-range physical maps, it should be mentioned that the YAC cloning system is not perfect. A percentage of clones within a YAC library are chimeric; that is, their inserts are composed of two or more unrelated genomic fragments that have become ligated together as an artifact of the cloning process. The preidentification of chimeric clones is essential before one can begin to generate a physical map. The disadvantages (e.g., the chimerism and the instability) can limit the utility of YAC libraries and restrict their purposes.

Two other systems for cloning large genomic inserts have been described more recently, which offer high clonal stability, reduced cloning biases, and are easily purified for DNA sequencing: the PAC (bacteriophage P1-derived artificial chromosomes) (Ioannou *et al*., 1994) and BAC (bacterial artificial chromosomes) (Shizuya and Kouros-Mehr, 2001).

The PAC system is based on the use of the bacteriophage P1 as a cloning vector (Pierce *et al*., 1992; Pierce and Sternberg, 1992). This system has been used to obtain a mouse genomic library with average inserts in the range of 75–95 kb with a maximum cloning capacity of 100 kb. The P1 cloning system has two advantages over YACs: first, it has much more efficient cloning rates, and second, like other bacterial cloning systems, it allows the efficient purification of large amounts of clone DNA away from the rest of the bacterial genome. The utility of this cloning system in the analysis of genomic organization within the H2 region has been demonstrated (Gasser *et al*., 1994).

The BAC system (bacterial artificial chromosome) is derived from the well-studied *E. coli* F factor, which is essentially a naturally occurring single-copy plasmid (Shizuya *et al*., 1992). This plasmid has been converted into a vector that allows the cloning of inserts with more than 300 kb of DNA, and with a reported average size range of 200–300 kb. The BAC system has the same advantages as P1 and the added advantage of a larger potential insert size.

4. Physical mapping

Physical mapping is a means to map genes or DNA sequences on a chromosome without relying on meiotic segregation (genetic mapping). Physical maps provide molecular access to chromosomal regions of interest and therefore facilitate the positional cloning of genes. Ideally, the series of clones should be gap-free and form a contiguous clone array. For the analysis of a specific chromosomal region, like QTL regions, a high-resolution physical map is desirable. A series of identified clones are assembled to provide a full representation of the region of interest.

Common physical mapping strategies (*see* Article 9, **Genome mapping overview**, Volume 3) are based on the PCR screening of large-insert cloning libraries using appropriate markers. An extremely powerful and convenient tool for ordering sequences according to their chromosomal position is a radiation hybrid panel (*see* Article 14, **The construction and use of radiation hybrid maps in**

genomic research, Volume 3). The localization of any STS can be achieved by PCR amplification and scoring of a particular radiation hybrid panel. The obtained patterns are compared with patterns of previously mapped markers held on a central server.

4.1. PCR-based STS mapping

STS content mapping involves scoring a series of clones for the presence or absence of particular STSs. STS content mapping is often used as a tool to assemble clone contigs. Large-insert genomic libraries (e.g., YAC libraries) are usually screened by PCR to amplify specific sequences contained within the genomic clones. These STSs serve as unique identifiers to ascertain whether the DNA fragments are located within other genomic clones to establish an overlap between clones. The number of PCRs for library screening can be significantly reduced by pooling YAC clones (see Figure 1).

Chromosomal walking by clone–clone hybridization is not practically feasible with mammalian YACs: the large amount of repetitive DNA in the inserts means that blocking of the repetitive DNA signal during hybridization is technically difficult. Instead, techniques are used to recover short-end fragments from individual YACs, for example, by restriction enzyme digestion or PCR amplification. Usually, the YAC DNA is cleaved with a restriction enzyme that is known to cleave the YAC vector sequence. Among the cleavage products, there will be fragments containing both the unknown terminal sequence from the insert DNA and the adjacent known vector sequence. Such sequences can be amplified using various PCR-based methods by using a primer binding to the vector sequence to permit access to an adjacent uncharacterized sequence (e.g., Inverse-PCR, Vectorette PCR).

YAC insert end fragments can then be used as hybridization probes to screen colony filters from a YAC library (see Section 4.2 below), or are sequenced to design oligonucleotide primers to permit a PCR assay for this sequence. PCR can then be used again to screen pooled libraries for identifying YAC with overlapping sequences. All positive clones from a YAC, or other large-insert libraries can be sized by PFGE, and fragments at both ends of each insert can be isolated rapidly by several standard protocols (Riley *et al*., 1990; Cox *et al*., 1993). End fragments from each clone should be used as probes to perform an initial test of the possibility of chimerism. This can be accomplished by probing appropriate somatic cell hybrid lines to determine whether both ends map to the same chromosome as the original DNA marker used to isolate the clone; if appropriate somatic cell hybrid lines are not available, one can also test the segregation of the end fragments on a panel of 20 interspecific (or intersubspecific) backcross samples. If the two end fragments show complete concordance in transmission, this can be taken as strong evidence for nonchimerism; in contrast, two or more recombination events would be highly suggestive of a chimeric clone. Chimeric clones need not be discarded; it is just necessary to be aware of their nature in any interpretation of the data that they generate.

The process of deriving YAC clones from a library can be brought to a halt when the clones that have already been obtained include the locus being sought.

It is only possible to reach this conclusion when the derived contig extends over markers that map apart from the locus on both of its sides. In other words, the contig must extend across the two closest recombination break points that define the outer limits of localization. If cloning is begun with a very dense map of markers placed onto a high-resolution cross, this endpoint is likely to be reached more quickly. With real luck, it might even be reached with the first set of YACs obtained in the initial screening of the library.

The interrepeat or interspersed repetitive sequence (IRS)-PCR is another means of isolating sequences that are specific to a chromosomal region of interest, for example, using somatic cell hybrids. IRS-PCR is an exceptional type of PCR in which genomic sequences located between two highly repetitive SINE elements are amplified (Ledbetter *et al*., 1990) (see Figure 2). The mammalian genome contains a large amount of highly repeated DNA sequence families, which are largely transcriptionally inactive. A wide variety of different repeats are known and they are classified into two major types of organization: tandemly repeated and interspersed repeated sequences. Tandemly repeated noncoding DNA is mainly grouped into three subclasses depending on the average size: satellite, mini-, and microsatellite DNA. Interspersed repetitive noncoding DNA sequences are not clustered, but are dispersed and a number of different classes exist. Most of the DNA families contain some members that are capable of undergoing retrotransposition (Deininger, 1989; Daniels and Deininger, 1985). Two major classes have been discerned on the basis of repeat unit length: SINEs (short interspersed nuclear elements) with an average size of 0.1 to 0.3 kb and LINEs (long interspersed nuclear elements) with an average size between 0.3 and 8 kb. The Alu element, with more than one million copies, is the most abundant SINE in humans. Because of the high copy number, the Alu gene family comprises more than 10% of the human genome (Lander *et al*., 2001).

IRS-PCR strategies have been applied to various species using the SINE sequences in human (Alu repeat) (Nelson *et al*., 1991), mouse (B1 repeat) (Hunter *et al*., 1996; McCarthy *et al*., 1995), rat (ID repeat) (Gosele *et al*., 2000), and zebrafish (DANA/mermaid repeat) (Shimoda *et al*., 1996). Since these SINE elements are present at a very high frequency in the respective genome, two of such repeats will often be found in close proximity and sometimes in opposite orientations. A single primer corresponding to a sequence close to the end of the repeat consensus sequence can bind to each of two closely located, oppositely orientated repeat sequences (Nelson *et al*., 1989). IRS-PCR can be applied on any genomic DNA template. If the starting DNA is complex (e.g., genomic DNA, cell hybrid DNA), the IRS-PCR will generate a series of bands that cannot be

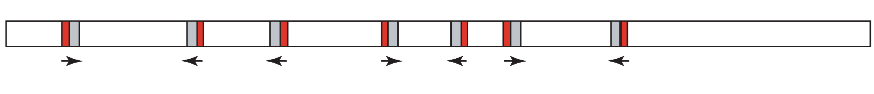

Figure 2 IRS-PCR permits amplification of DNA sequences located between two closely positioned but oppositely orientated repeat elements. A single primer corresponding to a sequence close to the end of the repeat consensus sequence can bind to each of two closely located, oppositely orientated repeat sequences. Amplification is carried out with a single primer complementary to the 5′-3′ repetitive element

resolved by conventional agarose gel electrophoresis. The size of amplified IRS-PCR products ranges from 200 to 2000 bp. If IRS-PCR is carried out on low-complexity templates (e.g., YAC, PAC or BAC clones), one or a few products will be generated, which can directly be exploited as markers (Schalkwyk *et al*., 2001). The majority of IRS probes consist of unique single-copy DNA sequences (except for incorporated primers). Therefore, IRS-PCR products from large-insert genomic clones can be compared with equivalent products from other library clones to check for overlapping clones based on IRS amplification products in common, and also used as hybridization probes for screening large-insert clone libraries (see Section 4.2). The generation of large numbers of IRS markers is not only rapid but also cost-efficient, because there is no requirement to sequence markers or to design locus-specific primers.

4.2. Hybridization-based STS mapping

Once YAC clones are obtained by PCR-based screening of YAC libraries, YAC end fragments can be isolated as described above. YAC insert end sequences can then be used as hybridization probes to screen colony filters from a YAC, PAC, or BAC library to identify adjacent clones.

An alternative strategy for integrated physical and genetic mapping is based on the interrepeat or interspersed repetitive sequence (IRS)-PCR system, which enables a high-throughput screening of large numbers of clones in a time and cost-efficient way by hybridization.

The IRS-PCR-based physical mapping strategy relies on the ability to detect clone overlaps by hybridization of an individual IRS-PCR product to IRS-PCR product pool filter. Therefore, coordinate pools that define a library are amplified with the repetitive element primer. These IRS-PCR pool products are spotted onto nylon membranes in ordered arrays. Individual IRS-PCR products of clones (previously mapped) are utilized as hybridization probes to identify overlapping clones. Overlapping clones are then amplified again via IRS-PCR and PCR products are used as hybridization probes (see Figure 3). Clone contigs are built by repeating these rounds of PCR and hybridization. Chromosome walking based on IRS-PCR and hybridization is bidirectional and, therefore, highly efficient.

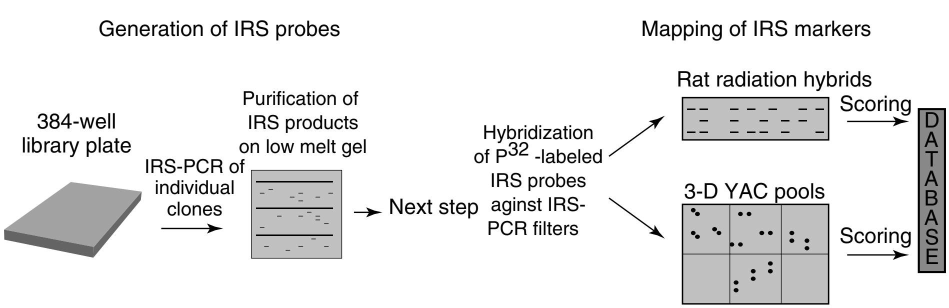

Figure 3 Schematic representation of the IRS-PCR-based physical mapping strategy for the construction of an integrated radiation hybrid and physical map

The main advantage is that this approach permits the simultaneous screening of multiple probes and/or libraries in one hybridization step, avoiding running of gels, sequencing, and primer design. This technology was utilized for the construction of clone contigs in mouse (Hunter *et al*., 1994), physical mapping of the mouse (Hunter *et al*., 1996; McCarthy *et al*., 1995; Schalkwyk *et al*., 2001) and the rat genome (Krzywinski *et al*., 2004). For the physical mapping of the rat genome, two mapping methods were combined to gain information about the proximity of marker loci: YAC libraries were screened by hybridization-based assays to identify clones containing a given locus. Nearby loci tend to be present in many of the same clones, allowing proximity to be inferred. Marker-content linkage can be detected over distances of about 800 kb, given the average insert size of the YAC library used (Figure 4).

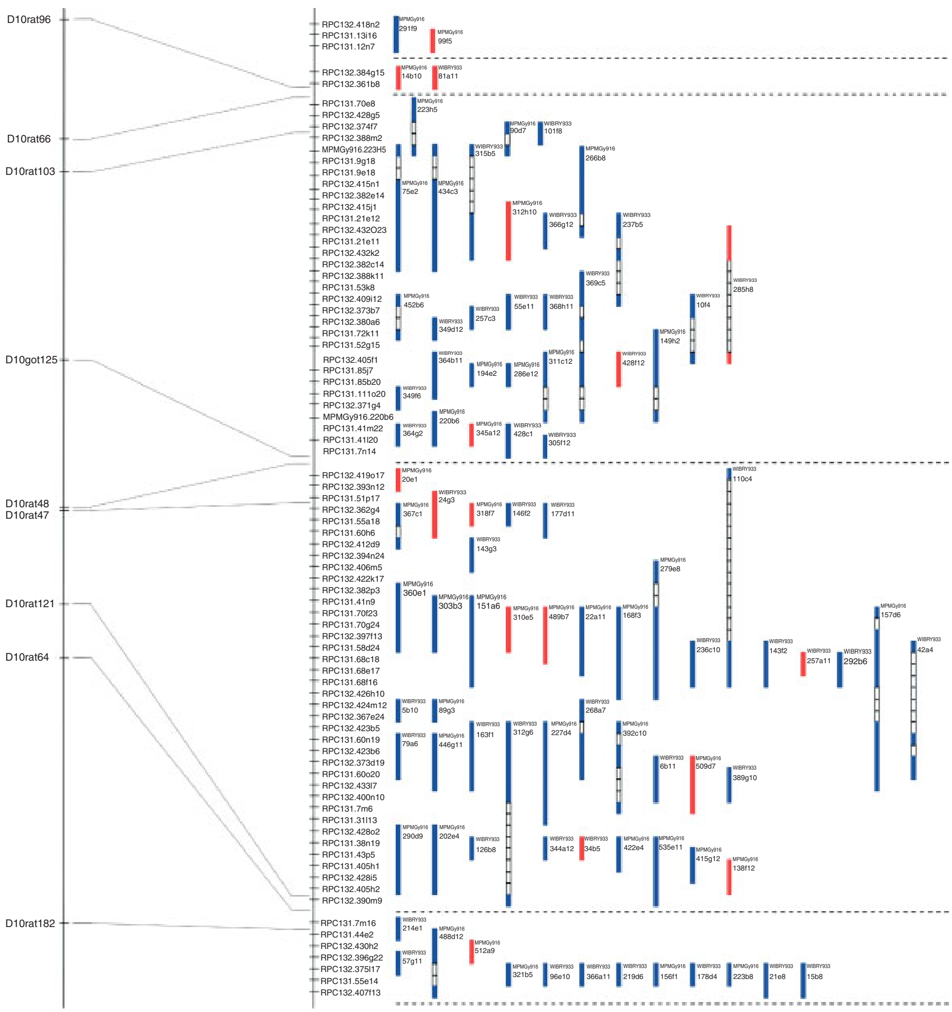

Figure 4 YAC contig of a region of the rat chromosome 10, constructed by IRS-PCR-based physical mapping

Hybrid cell lines, each containing many chromosomal fragments produced by radiation breakage, are screened to identify those hybrids that have retained a given locus. Nearby loci tend to show similar retention patterns, allowing proximity to be inferred. RH linkage can be detected for distances of about 2–3 Mb, given the average fragment size of the RH panel used. For the construction of a physical map and assembly of contigs, YAC clones with positive hybridization signals are considered. The number of YAC clones has to be pruned with considerable care toward chimeric clones, an inherent problem with any YAC library (Green *et al*., 1999). The final map of each chromosome can be constructed by integrating the YAC-linkage information with the known radiation hybrid map positions of the IRS markers using, for example, the co2 software package (Hudson *et al*., 1995). Doubly linked contigs are identified and then single linkage information is used to join doubly linked contigs known to lie nearby.

The primary goal of physical mapping is to assemble a comprehensive series of DNA clones with overlapping inserts. Clone-based laboratory methods maintain an important component to study large genomes through applications such as fluorescent in situ hybridization and comparative genomic hybridization. Physical maps provide an ordered, high-resolution, redundant clone set spanning the entire genome, which will be an important resource for the easy identification and access to clones spanning regions of interest in the relevant genome. The generation of in-depth physical maps will therefore continue to be a desired component for functional genomics.

Specialist Review

The construction and use of radiation hybrid maps in genomic research

Mathieu Gautier and André Eggen
Laboratoire de Génétique Biochimique et de Cytogénétique, Jouy-en-Josas, France

1. Introduction

At the beginning of the sixties, Barski *et al*. (1960) reported the occurrence of spontaneous cellular fusion events. A few years later, new methodologies using Sendai virus inactivated by UV (Yerganian and Nell, 1966) or polyethylene glycol (PEG) treatments made it possible to induce cell fusion and to produce heterocaryotic somatic hybrid cells (Pontecorvo, 1975). In addition, hybrid cells, originally called recombinant cells, could be separated from the parental cells from which they originated by culturing the cells in selective media. In 1975, Goss and Harris proposed for the first time the use of these techniques for genetic mapping purposes: they had observed that lethally X-ray irradiated donor cells could fuse to a receptor cell giving rise to a viable hybrid cell line. This so-called radiation hybrid (RH) cell line possessed a heterocaryon with chromosomes corresponding to a mosaic of chromosome fragments from the donor and the receptor cells: the stronger the irradiation dose, the shorter the average expected size of the donor chromosome fragments was. The principle is thus very similar to the classical linkage mapping strategy since X-ray induced breakage points mimic recombination points produced during meiosis.

In this review, we will consider the main principles of the construction and characterization of RH panels, their advantages to other mapping tools for the development of high-resolution genetic and comparative maps, and their possible contributions in different genome mapping projects.

2. Construction of RH panels: principles

2.1. Production and selection of RH cells

As shown in Figure 1, nucleotide biosynthesis can be accomplished through two biological pathways, that is, the main and the salvage pathways. In selective HAT (Hypoxanthin Aminopterin Thymidine) medium, aminopterin blocks the main pathway while the two precursors (hypoxanthin and thymidine) are available for the

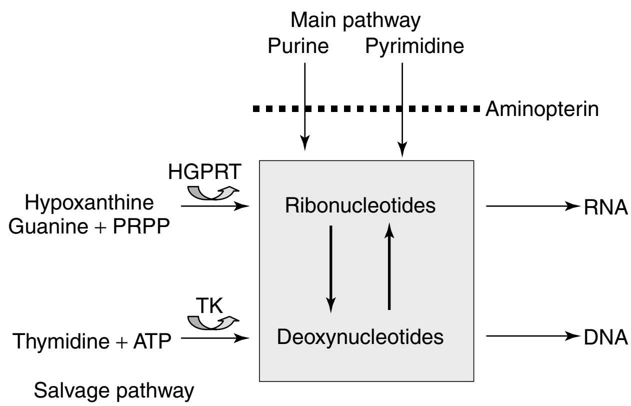

Figure 1 Nucleotide biosynthesis pathway. In the selective HAT medium, the main pathway is blocked by aminopterin (A of HAT), a structural analog of folic acid. Cells need the two precursors hypoxanthine (H of HAT) and thymidine (T of HAT) to produce respectively ribo- and deoxyribonucleotides through the salvage pathway. Mutant cells deficient, either for HGPRT (hypoxanthine-guanine phosphoribosyl transferase) or TK (thymidine kinase), cannot use the salvage pathway and thus will die

salvage pathway. To construct an RH cell line, the chosen receptor cell line (usually hamster or mouse) is deficient either for thymidine kinase (TK) or hypoxanthine-guanine phosphoribosyl transferase (HGPRT). After X-ray irradiation of the donor cells from the species of interest, usually with a dose between 3000 and 12 000 γ-ray Rad, a fusion with the receptor cells is induced. When grown in selective HAT medium, nonfused (tk^- or $hgprt^-$) receptor cells lacking one of the two key enzymes for the salvage pathway and lethally irradiated nonfused donor cells will be counterselected. Only RH cells in which the deficient *tk* or *hgprt* gene from the receptor cell has been complemented by its functional counterpart carried by one of the integrated chromosomal donor fragments will then survive (Figure 2).

During the culture of RH cell lines, chromosomal segments originating from the donor cells are randomly eliminated, while chromosomes from the receptor cell are conserved. To our knowledge, the mechanism behind this phenomenon has not yet been elucidated. Consequently, each independent RH cell line constituting an RH panel (usually composed of about one hundred lines) will contain a different set of chromosomal segments from the donor genome. Nevertheless, a bias will remain for the genomic region containing the marker gene of selection (e.g., in man, *tk* and *hgprt* are respectively located on HSA17 and HSAX chromosomes and, therefore, the corresponding regions will be preferably retained).

From a practical point of view, to allow for experimental replication and data comparisons using the same lines, it is important to extract sufficiently large quantities of DNA from each line since additional rounds of culture of the RH cell lines will lead to a set of donor chromosomal segments different from the original one. The main principles of the production and selection of RH cell lines are summarized in Figure 2.

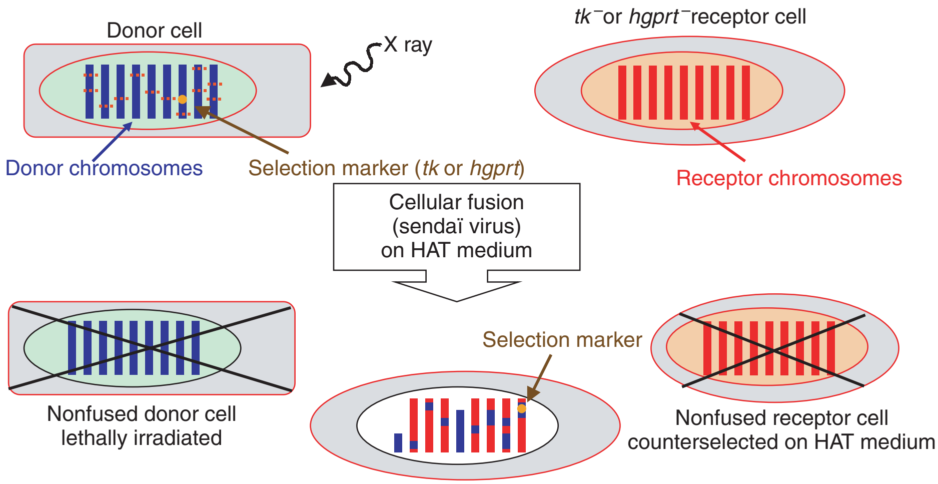

Figure 2 Schematic representation of the construction of RH cell lines

2.2. *"Haploid" and "diploid" RH panels*

Although the principle of producing radiation hybrids was known since the middle of the 1970s, the use of RH panels to construct maps remained limited for about 15 years owing to the paucity of available genes and markers and the fact that PCR was not yet a mature technology. In 1990, Cox and coworkers were the first to demonstrate the feasibility of producing an RH panel and its efficiency to construct an RH map of human chromosome 21 (HSA21). They also presented the first principles of the statistical tools necessary for mapping a marker. For this large-scale RH panel, the donor cells were obtained from a somatic hybrid cell line carrying a "haploid" copy of HSA21. After irradiation with a dose of 8000-Rad X ray and fusion with a rodent receptor cell line, the authors produced 103 haploid RH cell lines, which were found to randomly retain between 30 and 60% of human chromosome 21.

At that point, the generalization of this procedure to produce whole-genome RH panels (WGRHP) was not straightforward since monohybrid somatic cell lines were difficult or nearly impossible to produce for most species. Thus, too many RH lines would have to be produced for the panel to be efficient. A new strategy, consisting of using donor cells derived from diploid cell lines (human fibroblasts), was then developed resulting in "diploid" RH cell lines (Walter *et al*., 1994). It is interesting to note that this methodology is very similar to the initial proposition made by Goss and Harris (1975). This new strategy was then used to generate RH panels for many different species such as mouse (Schmitt *et al*., 1996; McCarthy *et al*., 1997), cattle (Womack *et al*., 1997; Rexroad *et al*., 2000; Williams *et al*., 2002), dog (Priat *et al*., 1998), pig (Yerle *et al*., 1998; Yerle *et al*., 2002), rat (Watanabe *et al*., 1999; McCarthy *et al*., 2000), cat (Murphy *et al*., 1999), horse

Table 1 Overview of some whole-genome radiation hybrid panel (WGRHP) available in different species

Species	Reference	Irradiation dose (Rad)	Number of lines	Mean estimated retention frequency	kb/cR[a]	Resolution kb[b]
Cat	Murphy *et al*. (1999) Murphy *et al*. (2001)	5000	93	0.39	195	538

[a]In some cases, we assume 1 cM is equivalent to 1 Mb to estimate the ratio kb/cR.
[b]The resolution was estimated as the average size of retained fragments (=100 times the ratio kb/cR following the definition of the unity cRay) divided by the product of the number of lines and the average retention frequency.

(Kiguwa *et al*., 2000; Chowdhary *et al*., 2002), macaque (Murphy *et al*., 2001), zebra fish (Geisler *et al*., 1999), and chicken (Morisson *et al*., 2002). Table 1 presents an overview of the different WGRHP panels available for the species cited above.

3. RH mapping methodology

3.1. *Definition and control of the parameters of interest*

RH mapping methodology is mostly inspired by the linkage mapping methodologies leading to a similarity in terminology in both cases. The two important parameters to be considered in RH mapping are the probability of breakage between two markers and the retention probability of the donor chromosomal segment (Figure 3).

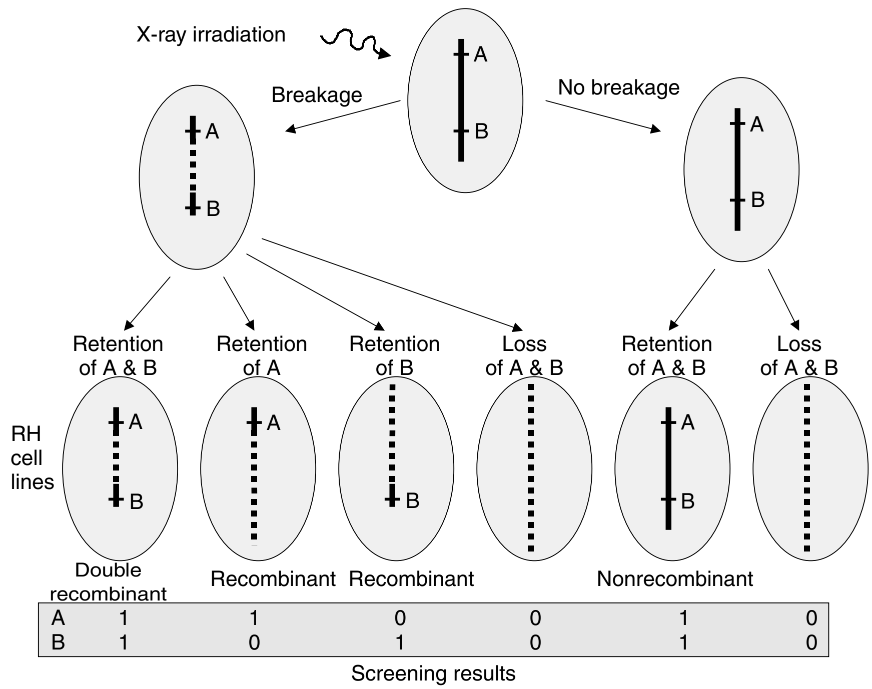

Figure 3 RH mapping principles. Breakage points generated by X-ray irradiation in the donor cells mimic meiotic recombinations, and it becomes possible for a given chromosomal segment (here between markers A and B) to sort out nonrecombinant "parental" haplotypes (no breakage between A and B and the resulting segment is retained or eliminated) and "recombinant" haplotypes (breakage between A and B and only one marker is retained). The analogy with linkage mapping can be further prolonged with the identification of "double recombinant" RH cell lines (breakage between A and B and they are retained or eliminated together). Observable results from RH panel screening for the presence/absence of markers are shown on the bottom of the figure

3.1.1. Breakage probability

The breakage probability is dependent both on the physical distance separating markers and the irradiation dose used to generate the panel: for a given X-ray dose, the closer the two markers are, the lower the probability of breakage between them and the larger the probability of coretention or coelimination. The breakage probability varies from 0 if the markers are at the same position to 1 if markers are segregating independently since their co-retention is only dependent on the retention probability.

Distances in RH maps are measured in $cRay_{xRad}$. 1 $cRay_{xRad}$ corresponds to a breakage probability of 1 % between two markers in a panel constructed with a γ-ray dose of x Rad. In theory, it is possible to control the resolution of the panel by controlling the irradiation dose; however, it should be noted that the reproducibility using the same irradiation dose among laboratories appears to be far from perfect and the DNA fragmentation due to the irradiation dose seems to depend on donor cells. Therefore, the resolution of a 3000-Rad panel may be the same as that of a

5000-Rad panel or even higher (see Table 1). Moreover, the expected resolution has to be adjusted according to the number of markers available or expected.

3.1.2. Retention probability

The different X-ray induced "recombinant" or "nonrecombinant" chromosomal segments from the donor cell can be detected only if they are retained in the RH cell lines considered (see Figure 3). Thus, the probability of retention introduces a second level of control to achieve a good resolution for the RH panel. This parameter can be compared to the number of individuals needed in a linkage mapping experiment to obtain a sufficient number of informative meiosis. Nevertheless, since the mechanisms of elimination of chromosomal segments during RH cell growth remain poorly understood, the retention probability in the RH panel can be controlled during its construction by operating a selection among the RH cell lines available. This should be done carefully to avoid introducing a bias in further analyses (for instance, by screening a small set of independent markers to estimate the overall retention probability of each RH cell line produced).

3.2. Parameters estimation

Statistical methodologies for RH mapping are identical to the ones used classically in linkage mapping and developed in the beginning of the 1990s (Boehnke *et al*., 1991; Cox *et al*., 1990; Lunetta and Boehnke, 1994; Lange *et al*., 1995). A description of these methodologies follows.

Screening the RH panel for a set of N markers permits the identification, for each pair of markers A_i and A_j (i and j varying from 1 to N), of four different types of RH cell lines (respectively $A_i^+A_j^+$, $A_i^+A_j^-$, $A_i^-A_j^+$, and $A_i^-A_j^-$ corresponding to the lines having retained respectively both A_i and A_j, A_i but not A_j, A_j but not A_i, and neither A_i nor A_j; Figure 3). However, it is not possible to estimate the parameters of interest directly from these four different populations of each of the four line types since it is not possible to directly distinguish between breakage and marker retention probabilities. Nevertheless, the expected number for each class can be calculated using as unknown parameters the breakage probability (θ_{ij}) between each couple of markers A_i and A_j, the retention probabilities r_i (respectively r_j) of marker A_i (respectively A_j) and the coretention probabilities r_{ij} ($i \neq j$) of A_i and A_j. These parameters are then estimated by maximizing the likelihood of the observations (see Cox *et al*., 1990 for detailed equations). Finally, assuming randomness of breakage events and no interference between them, breakage occurrence can be modeled as a Poisson process. The distance d_{ij} (in cRay_x, x being the irradiation dose in Rad) between markers A_i and A_j is thus $d_{ij} = -\log(1 - \theta_{ij})$. This function is analogous to the Haldane mapping function used in linkage mapping and computations of likelihood functions require the assumption of absence of multiple recombinations between markers that are responsible for nonadditiveness of two-point distances for physically distant markers. However, in

their pioneering experiment (14 markers covering 20 Mb on HSA21), Cox *et al*. (1990) showed that this effect appeared to be nonsignificant or negligible.

3.3. Linkage group construction (two-point analysis)

The first step in the construction of a map is to identify markers belonging to the same chromosome or to the same genomic region. Thus, two-point analyses consist of identifying, at a given threshold, a group of markers that are genetically linked. As in linkage mapping, for each of the $N(N-1)/2$ pairs of markers A_i and A_j, linkage is evaluated by calculating the Lod score (Lod_{ij}) corresponding to the log ratio of the likelihoods $L^1{}_{ij}$ of the data assuming linkage between A_i and A_j (alternative hypothesis H_1) and $L^0{}_{ij}$ of the data under the null hypothesis (H_0) of no corresponding linkage. Parameter values are those estimated as before for $H_{1,t}$ while a breakage probability of 1 is assumed to calculate H_0.

A linkage group at the S significance threshold will be defined by the L markers A_k (k varying from 1 to L with $L \leq N$) such that at least one marker A_l (l varying from 1 to L) gives $Lod_{kl} \geq S$. The number of linkage groups is thus increasing with S. It should be noted that for a given threshold (for instance $S = 3$), the linkage criterion is generally more stringent than in classical linkage mapping (Cox *et al*., 1990).

3.4. Determination of the order of markers inside a linkage group

As for linkage mapping, two families of methods are used to order markers inside linkage groups: nonparametric and parametric methods (Boehnke, 1992; Boehnke *et al*., 1991; Lange *et al*., 1995).

Nonparametric methods are based on an intuitive parsimony criterion consisting in finding the order among markers, which results in the minimum number of breakages in the RH cell lines of the panel. For instance, let us consider $N = 10$ markers screened on a cell line giving the result vector $\mathbf{h} = [1\ 1\ 1\ 9\ 0\ 9\ 0\ 0\ 1\ 1]$ (1 if the marker is present, 0 if the marker is absent, and 9 if the status of the marker is unknown). To explain **h**, at least two breakage points are necessary (one between marker 3 and 5 and one between 8 and 9, unknown breakpoints are ignored). The minimal number of breakages is called Obligate Chromosomal Break (OCB) and represents a minor of the actual number of breakages since double recombinants are ignored. To evaluate the OCB, one needs to count the number of times 0 (respectively 1) is followed by a 1 (respectively 0) in the result vector. The main advantage of this method is that the model considered is not restrictive (the only constraint is to ignore double recombinants), rather intuitive and not computationally intensive. However it provides no information about distances between markers.

Parametric approaches are generally based on the maximum likelihood principle. Thus, they define a stochastic model to sort the different possible orders according to the likelihood of the data. Several models have been proposed that differ by the number of parameters they impose for the estimation. In general, the hypothesis

aims at restraining the number of retention probabilities among markers. In the fuller model (Cox *et al*., 1990) named "general retention model", if N markers are considered, retention probabilities are estimated for all the $(N(N+1)/2)$ possible chromosomal segments (N possible segment with 1 marker; $N/2$ or $(N-1)/2$ if N is uneven containing $N-1$ markers; ... ; 1 possible segment containing all N markers). This model thus includes $(N^2+3N-2)/2$ parameters ($N-1$ breakage probabilities and $(N(N+1)/2)$ retention probabilities). When N gets bigger, it becomes quite computationally intensive, overparameterized and can only be applied in the case of "haploid" RH cell lines. Therefore, other simpler models have been proposed: the "equal retention probability model", the "centromeric or telomeric retention model", the "left-endpoint model", and the "selected locus model" (Bishop and Crockford, 1992; Chakravarti and Reefer, 1992; Lawrence and Morton, 1992; Boehnke *et al*., 1991; Boehnke, 1992; Lunetta *et al*., 1996). Some of these models are nested and thus can be compared relatively to each other.

Maximization of the likelihood for the different orders needs algorithmic computation. If comparison of the likelihood's among different possible orders permits to sort them, differences between the log-likelihoods of two consecutive orders may, however, be nonsignificant (for instance, at the significance threshold of 3). To circumvent this problem, a "framework map" can be constructed by selecting the K markers among the N ones such that the best order found has a log-likelihood superior to the one of the second order with a difference corresponding to the chosen threshold. Several software propose options to compute framework maps.

In the case of "diploid" hybrid cell lines, it is not possible (in general) to distinguish between lines having one copy of each marker and lines having two copies of the marker (each one from one of the two chromosome homologs of the donor cell). Thus, for parametric models, likelihood computation requires a hidden Markov chain algorithm (Lange *et al*., 1995). Nevertheless, in most cases, analysis of data from a "diploid" RH panel using haploid models does not seem to introduce differences in the best final order found (Ben-Dor *et al*., 2000) except a small underestimation of the distances between markers (about 5%).

Finally, when considering N markers, there are $N!/2$ possible orders to explore. Thus, whichever is the model chosen, evaluating all these orders to find the best one becomes quickly impossible. Some algorithms derived from combinatorial optimization under constraint (here either the number of OCB or the likelihood according to the model) were developed to decrease the number of orders to explore. A first class of methods based on the complete set of markers was proposed such as the "branch and bound", "stepwise locus ordering", or "simulated annealing" method (Nijenhuis and Wilf, 1978; Kirkpatrick *et al*., 1983; Barker *et al*., 1987). Recently, Ben-Dor *et al*. (2000) developed an algorithm based on the "Travelling Salesman Problem" (Garey and Johnson, 1979; Cormen, 1990). All these methods are heuristic and except for the ⟨ branch and bound ⟩ method, which is computationally intensive and practically impossible for a large set of markers ($N>10$), they do not guarantee that the best order will be found. Other heuristic (or metaheuristic) methods were proposed to try to improve a given order and to test if it is not suboptimal such as the "flip algorithm", "Tabu search", or "genetic algorithm" (Glover, 1986; Hansen, 1986; Holland, 1973; Barker *et al*., 1987).

In the end, once the best order is found, it is still possible to check the data by identifying unlikely recombinants, which can reveal a genotyping mistake. This type of a posteriori verification must however be undertaken carefully to avoid bias data.

3.5. Software

Several software packages are publicly available, and differ by the optimization algorithm or the options proposed. The most frequently used are:

- RHMAP (**http://www.spn.umich.edu/group/statgen/software**) contains three different programs, which can be freely downloaded: RH2PT (two-point analysis), RHMINBRK (order determination by a nonparametric approach), and RHMAXLIK (order determination by a parametric approach with almost all the models available).
- RHMAPPER (**http://www.genome.wi.mit.edu/ftp/pub/software/rhmapper**), which can also be freely downloaded. It uses a parametric strategy and a hidden Markov model to perform maximum likelihood calculations on multipoint maps (either on "haploid" or "diploid" panels). It is particularly suitable for large-scale mapping projects.
- RHO (**http://www.cs.technion.ac.il/Labs/cbl/research.html**), which should be used via a web interface. It uses the heuristic described in Ben-Dor *et al*. (2000), which can be applied on either parametric or nonparametric models.
- Carthagene (**www.inra.fr/bia/T/CarthaGene/**), which can be freely downloaded. This software is very user friendly and proposes many different construction procedures. It uses a parametric model with calculation times greatly decreased by an improvement of the EM algorithm (Schiex *et al*., 2002). However, like RHO it assumes that the panel is "haploid", but this does not seem to have a great influence on the reliability of the orders found (see above).

4. Advantages of RH mapping

RH mapping methodologies have met great success in many different species. This can be explained by several advantages as compared with classical linkage mapping strategies.

First, a panel consisting of 100 RH cell lines is in most cases sufficient to offer a good representation of the genome of interest, and its resolution (understood as the threshold at which two closely related markers will be distinguished) is higher than that of linkage mapping analysis. Indeed, in linkage mapping, the resolution is directly dependent on the number of informative meiosis in the pedigree analyzed (assuming an average correspondence of 1 cM and 1 Mb, to distinguish two markers, 1 Mb apart, it is necessary to have in theory 100 informative meiosis). If some markers are not informative in all the families of the pedigree analyzed, the number of individuals needed can therefore exceed greatly the number of informative meiosis wanted. Thus, the size of the experiment very often limits the resolution to the order of the centimorgans. In contrast and as explained above, a control of the irradiation dose and to a lower extent, the number of lines of the

RH panel make it possible to achieve a very fine resolution (up to less than 100 or 50 kb), the limit soon being represented by the number of markers available. Additionally, as far as we know, no hot or cold spot of X-induced breakages have been reported in genome-wide studies. As such, RH distances appear to be closely related with actual physical distances, and RH mapping is thus generally considered as a physical mapping method.

In practice, an RH panel is screened using several types of molecular methods: enzymatic expression analysis, probe hybridization, or more frequently PCR screening, which is easy and fast. One big advantage is that markers do not have to be polymorphic and hence all kinds of STSs (single sequence tags) and, in particular, coding sequences such as ESTs (expressed sequence tags) can be easily mapped on a broad scale. Additionally, detailed maps can be built for the non-pseudoautosomal part of sexual chromosomes such as the Y chromosome in mammals (Liu *et al*., 2002). These characteristics make it possible to use RH panel as an efficient and powerful tool to draw comparative maps through the use of comparative anchoring markers (O'Brien *et al*., 1993; Yang and Womack, 1998; Everts-van der Wind *et al*., 2004). The main principle is to choose markers in coding regions, permitting an easier identification of orthologies among genomes when the whole-genome sequence has not been sequenced. The only limiting factor of RH mapping is that if the species of the donor cells is closely related to the species of the receptor cells, the genome of the receptor cell may interact with the chosen probe. This can be avoided either by defining probes in the untranslated region of a gene, which has a lower level of sequence similarity (Wilcox *et al*., 1991) or in the case of PCR-based probes, by amplifying introns (using exonic probes) to generate an interspecific polymorphism (the intron length being less conserved). It is also possible to use more complex detection methods such as SSCP "single-strand conformation polymorphism", but then it starts to become more time consuming and labor intensive.

Finally, RH mapping constitutes an efficient tool to speed up positional cloning of genes affecting traits of interest, particularly if the sequence of the genome considered is not yet available or if only limited genome coverage is available (up to 2x coverage). RH mapping makes it possible to integrate both linkage and comparative maps thus to exploit efficiently both information sources. Indeed, the linkage mapping–related methodology permits the identification of genomic regions involved in the genetic determinism of the variation of a trait (QTL) using molecular markers and phenotypic information recorded on individuals of a given pedigree. An RH map including both markers used in linkage maps and comparative anchoring markers will permit anchorage of the identified genomic region on the genome of a different reference species and thus to benefit from the functional (identification of putative candidate genes) or, more generally, the mapping information available for this species.

5. Conclusion

Even if the completion of several whole-genome sequences appears to challenge the use of RH panels for positional cloning experiments, it should be noted that

they have played an active and important part in the history and success of these different genome projects, for example in man (Olivier *et al*., 2001) or recently, in rat (Kwitek *et al*., 2004). Indeed, with its high mapping resolution, contigs sequence assembly can be greatly speeded up or some inconsistencies resolved by screening on a given panel some relevant markers (from BAC end sequences or EST for instance).

Moreover, for most species for which no whole-genome sequence is available, the construction and use of an RH panel constitute a powerful tool for positional cloning strategies and more generally for making progress in genomic approaches. Notably, it produces a very fine resolution intermediate between that of linkage maps and BAC-based physical maps. The ease of screening and the fact that markers do not need to be polymorphic make it possible to develop fine whole-genome comparative maps. Thus, the species of interest can benefit from another better-characterized species to quickly build a physical map (Murphy *et al*., 2001). The only remaining limit is the number of available genetic markers, but the resolution of the panel can be adjusted by controlling the irradiation dose.

Specialist Review

Linkage mapping

Mark E. Samuels
Dalhousie University, Halifax, NS, Canada

Marie-Pierre Dubé
Institut de Cardiologie de Montréal, Montreal, QC, Canada

1. Introduction and scope

The purpose of this chapter is to provide a practical guide to linkage mapping for the identification of genes predisposing to human disease (or other interesting phenotypes). The emphasis will be on technical issues and pedigree-based analysis. More theoretical concerns, particularly those relating to methods in statistical genetics, will be covered in depth elsewhere (*see* Article 48, **Parametric versus nonparametric and two-point versus multipoint: controversies in gene mapping**, Volume 1, Article 52, **Algorithmic improvements in gene mapping**, Volume 1, Article 58, **Concept of complex trait genetics**, Volume 2, and Article 11, **Mapping complex disease phenotypes**, Volume 3). Alternative approaches such as linkage disequilibrium (LD) and SNP-based association mapping are covered in other chapters (*see* Article 12, **Haplotype mapping**, Volume 3, Article 17, **Linkage disequilibrium and whole-genome association studies**, Volume 3, Article 69, **Reliability and utility of single nucleotide polymorphisms for genetic association studies**, Volume 4, Article 73, **Creating LD maps of the genome**, Volume 4, and Article 74, **Finding and using haplotype blocks in candidate gene association studies**, Volume 4).

2. General approaches to linkage mapping

Linkage as a formal term refers to the mapping of a predisposing polymorphism or mutation at a genetic locus through the analysis of chromosomal segments transmitted to individuals with some known degree of relationship (Ott, 1991; Terwilliger and Ott, 1994) (see Figure 1). The enabling principle for linkage mapping in humans is the use of anonymous polymorphic DNA variants, called *markers*, as tags for these chromosomal segments (Botstein *et al*., 1980). Using these tags, one can detect the correlated inheritance of a particular trait with that of closely linked marker loci.

The genetic mapping described here results preferentially from the analysis of pedigrees showing Mendelian segregation of the trait of interest (*see* Article 51,

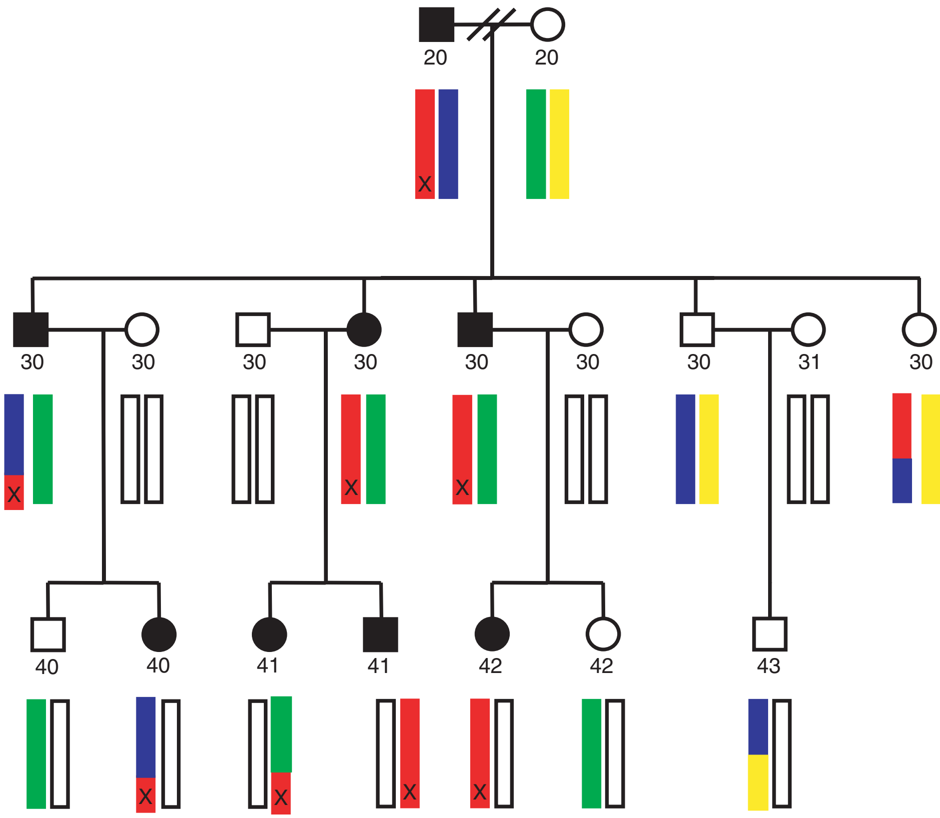

Figure 1 Schematic visualization of a pedigree segregating a biological phenotype of interest. According to convention, square symbols are male, circles are female. Affected individuals are shaded in black. The four hypothetical founding haplotypes for a given chromosome are indicated in red, blue, green, and yellow. Additional copies of this chromosome, introduced by spouses marrying into the pedigree, are displayed as unshaded bars. In this example, it is presumed that the affected founder is known for this pedigree (male in top generation). A causal mutation at a specific locus is presupposed by the X on the red haplotype. Recombination events reduce the extent of the red haplotype transmitted through the pedigree. In this idealized example, there is perfect cosegregation of the mutation (X) and a surrounding segment of red haplotype, in all affected individuals

Choices in gene mapping: populations and family structures, Volume 1 and Article 77, **Mechanisms of inheritance**, Volume 2). By this we mean: phenotypes are relatively straightforward to characterize; transmission in families is generally unilineal and unambiguous (although this can be confounded in some populations that exhibit high degrees of consanguinity); and underlying sequence variants usually confer obvious and severely deleterious effects on gene function (or in rarer cases obvious and severe gain of gene function). For the detection of linkage, large families have more statistical power than small ones, but these are not always available, especially for traits with low penetrance, delayed age of onset, or for traits of complex etiology (Haines and Pericak-Vance, 1998; *see also* Article 58, **Concept of complex trait genetics**, Volume 2 and Article 11, **Mapping complex disease phenotypes**, Volume 3).

3. Properties of genetic markers

Over the years, a variety of different genetic markers have been used for mapping purposes. For the past decade, the markers of choice for linkage have been microsatellite repeats, also known as VNTRs (variable number of tandem repeats) or STRs (short tandem repeats) (see Figure 2) (Litt and Luty, 1989; Taylor *et al*., 1989; Beckmann and Soller, 1990; Weber, 1990). They consist of stretches of repeating units such as CACACA or GATAGATAGATA, embedded within unique sequences in various chromosomal locations. For the most part, they lie outside the coding exons of genes, since varying repeat lengths other than triplets would otherwise lead to frameshift mutations. A particular repeat marker may be unambiguously detected using appropriately designed PCR primers in the surrounding unique sequence. These repeats frequently vary in length in different individuals, presumably because of occasional mistakes made by the replication machinery. Such events are relatively infrequent, so that these repeats are stable enough to be used in studies spanning multiple generations in a pedigree. They are not wholly stable however, and the identity of microsatellite alleles by state is usually not sufficient to infer identity by descent in individuals of distant

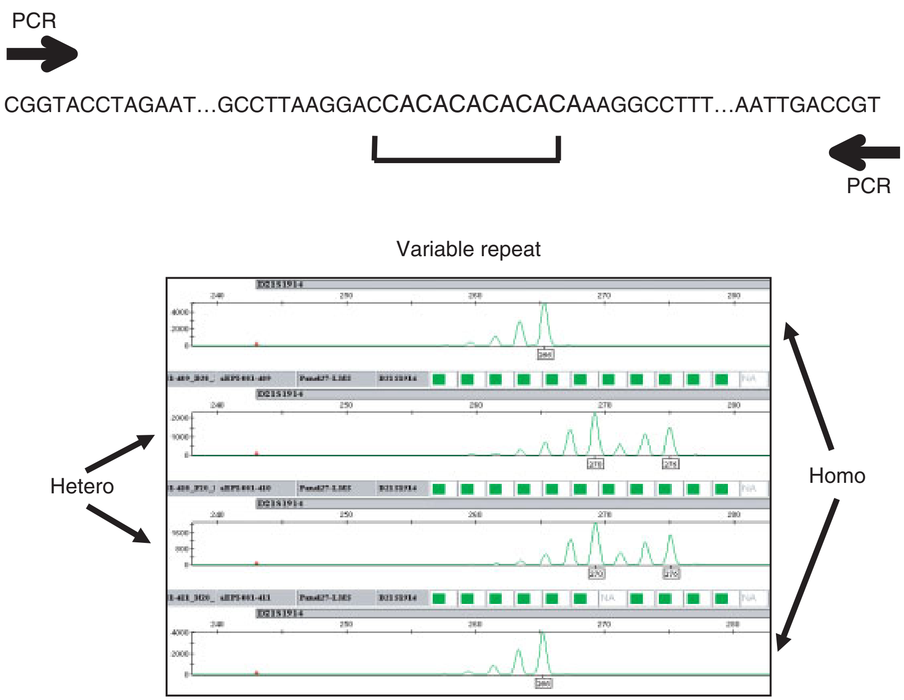

Figure 2 Typical dinucleotide microsatellite repeat marker. A (CA)n repeat is embedded within a unique sequence context, which provides for the development of marker-specific PCR amplification primers. Below is a chromatogram for a real dinucleotide repeat, D21 S1914, located on chromosome 21. Genotypes are shown for four individuals, first and fourth are homozygotes, second and third are heterozygotes. Relative allele sizes (i.e., names) are indicated in small black boxes below the highest molecular weight peak for each allele. (Courtesy of J. Thompson.)

or unknown genealogical relationship (with exceptions in founder populations). In order to be useful in linkage analysis, a marker must have multiple alleles present in a population. The more alleles the better; however, owing to the limitations of analytical approaches, it is usually best to use markers with no more than 12–15 alleles. The information content of markers is commonly measured using the heterozygosity value and the polymorphism information content (PIC) value. Dinucleotide microsatellites are typically more informative than tri- or tetranucleotide repeats, with heterozygosities as high as 0.7–0.8.

It is estimated that the human genome has 5000–10 000 such microsatellite repeats. For these markers to be used in a genetic mapping study, their relative order and distance along each chromosome must be known. Several genetic maps have been generated, through marker genotyping in large families with multiple meioses, and using recombination data to orient and locate markers with respect to each other (Weissenbach *et al*., 1992; Gyapay *et al*., 1994; Broman *et al*., 1998; Yu *et al*., 2001; DeWan *et al*., 2002; Kong *et al*., 2002). Now almost all markers can be placed unambiguously on the assembled human genome sequence.

The human nuclear genome consists of approximately 3600 centimorgans (cM) in genetic distance (averaged over both sexes) (Kong *et al*., 2002). Thus, to cover the genome at 10-cM resolution requires 360 genetic markers, assuming each is fully informative; 5-cM resolution requires 720 markers. Good microsatellites of high information content come close to these limits, hence genome-wide mapping panels have on the order of 400 (10 cM) to 800 (5 cM) markers respectively. Such sets are commercially available (Reed *et al*., 1994; Lindqvist *et al*., 1996).

The general approach to a linkage mapping experiment is to perform a whole-genome scan at approximately 5- or 10-cM density on a set of samples from one or more families transmitting the phenotype of interest. Following statistical analysis, potential regions of linkage are identified on various chromosomes. Each of these is subjected to genotyping of additional microsatellite markers at increased density, followed by reanalysis. Ideally, only a single region survives the second round of mapping. A third round of genotyping with an increased density of markers, potentially exhausting all microsatellite repeats in a region, may follow. Owing to the relatively high cost of complete genome scans, often only subsets of sampled individuals are genotyped in the initial phase, focusing on those carrying the most definitive phenotypic state.

In some situations, linkage analysis may begin with or be restricted to specific genes with a higher biological probability of involvement in the phenotype, often termed candidate genes. The general principles of mapping are the same, but practically this reduces the scope of genotyping to smaller sets of markers near these genes, with potentially significant cost savings. Often, this approach is used to exclude genes already known to mutate to the phenotype of interest, in newly ascertained families.

For fine-mapping of recombination events in specific meioses, commercially available genome scan panels have insufficient resolution. Therefore, laboratories involved in linkage mapping must develop additional custom markers. Public databases include many thousands of potentially available microsatellite markers that can be used for such fine-mapping. These are typically identified with a “D” number such as D1 S2134, indicating the chromosome such as chr1 plus the specific

marker number – however, some nonpolymorphic PCR amplification products or sequence tagged sites (STSs) were historically assigned D numbers; thus, such numbers are not automatically indicative of microsatellite repeat status. Moreover, some useful markers have never been assigned D numbers but retain only the numbers from the projects in which they were developed, such as Utah markers (UT numbers) (Utah Marker Development Group, 1995), Marshfield markers (Mfld numbers) (Broman *et al*., 1998; Weber, 1990; Weber and Broman, 2001; DeWan *et al*., 2002), and Genethon markers (AFM numbers) (Weissenbach *et al*., 1992; Gyapay *et al*., 1994; Reed *et al*., 1994). Current databases attempt to unify all known markers and aliases for each marker, but it is not necessarily true that two differently named markers are truly different.

Once all identified markers in a region have been exhausted, the genome sequence in chromosomal regions of interest can be directly examined for additional microsatellite motifs using standard bioinformatics tools. The total potential resolution of microsatellite markers is on the order of 0.2 to 1 cM, which is typically sufficient for positional cloning purposes. Recall that the smallest definable interval containing a putative causal variant is a function of recombination events that have occurred in meioses between the patients who have been sampled. The actual size of the recombinant interval is not dependent on the density of markers being used to analyze it. Only the resolution with which the exact site of recombination is mapped is affected by the density of markers employed.

Recently, commercial mapping panels of single-nucleotide polymorphisms (SNPs) have begun to come into use for linkage mapping (Tsai *et al*., 2003; Sellick *et al*., 2004). A single microsatellite marker is often considered to have equivalent information content to 3–4 SNPs. SNP technologies will not be reviewed here (*see* Article 50, **Gene mapping and the transition from STRPs to SNPs**, Volume 1), however, whole-genome mapping sets are now commercially marketed. These sets initially contained in the range of 4–10 000 SNPs, roughly equivalent to a 5-cM microsatellite genome scan, and are designed for family-based linkage analysis. More recently, SNP panels of 100 000 markers have been developed. As SNPs are generally biallelic, it is intrinsically more straightforward to generate allele calls, so manual review may be unnecessary at least for standardized marker sets. SNPs are believed to be stable over long periods of time. A given SNP is usually presumed to have arisen once only during evolution (although some nucleotide positions may turn out to be unstable and mutate repeatedly). Thus, identity of state for an SNP site in two individuals is considered to be indicative of identity by descent. For fine-mapping equivalent to microsatellites at about 1-cM resolution, hundreds of thousands to millions of potential SNPs are available in public databases, however, the informativeness of these must be evaluated for specific patient samples in a family-mapping study (Sachidanandam *et al*., 2001; Holden, 2002). Even if SNP sets become the standard tool for low-resolution genome scanning, microsatellites will probably continue to play a useful role in fine-mapping for this reason.

4. Microsatellite genotyping

Microsatellites are typically assayed following PCR. One of the PCR primers is usually tagged with a fluorescent dye, and the products of PCR are resolved

electrophoretically either on polyacrylamide gels or by capillary electrophoresis (Ziegle *et al*., 1992; Gelfi *et al*., 1994; Reed *et al*., 1994; Gyapay *et al*., 1996; Lindqvist *et al*., 1996; Mansfield *et al*., 1996; Ghosh *et al*., 1997; Mansfield *et al*., 1997; Vainer *et al*., 1997; Wenz *et al*., 1998; Delmotte *et al*., 2001; Wenz *et al*., 2001). Although the concept is straightforward, there are potential technical pitfalls.

PCR primers must amplify the marker in question with high specificity. Ideally, both primers should lie in unique sequence; however, in practice, this is sometimes difficult to achieve as microsatellites often lie in or near repetitive elements. Hence, PCR conditions may require optimization to generate sufficiently specific products. For genome scan mapping panels, standardized conditions have been developed and are available, although laboratories should be prepared to reoptimize if needed. In developing custom microsatellite markers for fine-mapping, laboratories must usually develop their own PCR conditions. One may move PCR primers in addition to altering reaction conditions, as long as the primers remain specific to the repeat unit under development. Indeed, the exact primer sequences of commercial marker kits may be proprietary and different from public database primers for those markers.

When DNA is extracted from patient blood samples, both maternal and paternal chromosomes are recovered, hence both alleles of a microsatellite marker are observed. On occasion, genotyping may employ DNA from single sperm cells, or from cell lines reduced to haploidy through cell fusion and chromosome loss. But for linkage analyses, blood samples are the usual source. Inactivation of X chromosomes in females presents no problem.

A typical dinucleotide chromatogram is shown in Figure 2, with examples of homozygous and heterozygous individuals. Although unique products have been amplified, note that there are multiple peaks even in the homozygotes. Extra so-called stutter peaks are observed, smaller than the full-length product, and presumed to result from enzymatic skipping during PCR. The spacing of stutter peaks is equivalent to the type of repeat unit. Stutter peaks do not generally impede genotyping. The size of a microsatellite allele is usually defined by the position of the largest molecular weight peak.

The enzymes typically used in PCR have a tendency to add additional, nontemplated nucleotides at the 3′ ends of products, to a variable extent. Thus, microsatellite chromatograms historically have suffered from the problem of "peak-splitting". This is separate from and in addition to the observation of stutter peaks. If this problem is severe enough, particular markers may be wholly useless. Specific added sequence elements can reduce the intrinsic variability of nontemplated addition. These sequence elements are added to the 5′ end of the nonlabeled PCR primer, so that variability in nontemplated addition is reduced at the 3′ end of the labeled strand, which is the strand visualized by the instrumentation (see Figure 2) (Brownstein *et al*., 1996; Magnuson *et al*., 1996).

Despite optimization, some markers do routinely give extra peaks, presumably because of additional priming sites in the genome. Such markers may still be useful if these peaks are sufficiently reproducible. However, automated genotyping programs may require additional training to deal with them. In some cases, extra peaks fall into the expected allele range for other markers multiplexed with the marker in question.

Microsatellite genotype calls, usually given in base pairs, are not exact but are relative to internal size standards, and as such are only indirect readouts of the actual number of repeats in a given allele in a given sample. These size standards may be purchased from commercial suppliers or synthesized in the laboratory (Brondani and Grattapaglia, 2001). Unfortunately, the interpolation of allele sizes is dependent on the specifics of the electrophoretic system used. Thus, genotypes are difficult to compare between different instrument platforms, and often between different laboratories' versions of the same marker. One solution to this is to normalize all allele calls for a given marker to a standard DNA sample, such as a CEPH control DNA. This technique allows data to be pooled across multiple platforms, although standardized calls may need to be created independently for each different instrument.

To increase efficiency, multiplexing is typically performed. Unfortunately, microsatellites have proved recalcitrant to pre-PCR multiplexing. Therefore, multiplexing of microsatellites is usually performed after PCR and prior to electrophoresis.

Since multiplexed markers are subjected to electrophoresis in the same lane or capillary, it is critical to associate specific chromatogram peaks with the correct marker. Allelic size ranges are determined for a specific PCR primer pair used to amplify a marker, either based on public information or else by test genotyping a set of random control DNAs. Thus, peaks for a specific marker have an expected size range where genotypes are called. However, novel alleles are often observed when large numbers of experimental samples are subsequently genotyped for that marker. Some of these alleles may fall outside the expected range for that marker. In this case, trained software must be updated to incorporate the new alleles, which can be problematic if there is overlap with other markers that were previously multiplexed in the same lane. This problem is often identified through the failure of a marker neighboring the actual marker with the allelic expansion. In the worst case, individual markers may have to be removed from a multiplexed panel and electrophoretically analyzed separately. To minimize potential for subsequent allelic overlap, when a new panel of multiplexed markers is developed, a gap should be provided between the known ranges of size-adjacent markers.

Multiplexing also relies on the availability of multiple fluorescent dye tags with different emission spectra. Markers with overlapping size range but different dye tags may thus be pooled. Commercial systems typically permit four different dyes to be multiplexed, one of which is used for the internal size standard. The various fluorescent dyes alter the mobility of DNA fragments, so that the apparent electrophoretic mobility of a given marker will change if a different dye is substituted. A similar and even more severe problem may arise if the dye tag or spacer structure is altered on the internal size standard, in which case ALL marker mobilities may have to be redefined.

Commercial mapping panels have been optimized for marker dye color and spacing so that as many as 15–20 different microsatellites may be assayed in the same lane, significantly reducing cost and enhancing throughput. With effort, custom panels can also be highly multiplexed, although this may not necessarily be cost-effective.

Following electrophoresis and data collection, actual genotype calls must be made. This can be performed either fully manually or semiautomatically. Commercially available software packages exist for automated genotype calling (Applied Biosystems GeneMapper, SoftGenetics GeneMarker), but while effective, these packages require caution in actual use. In practice, some amount of manual review is always necessary, particularly for markers with complex chromatograms or extra peaks. Nonetheless, current software genotyping programs can be very efficient in reducing the required amount of manual trace review for well-behaved markers or markers with which laboratories have extensive experience.

It is recommended that if primers are redesigned, version numbers be used explicitly. It can be highly confusing if multiple versions of a marker, with slightly different primer sequences and or dye types, have the same name in a laboratory system. Version numbers may need to be removed prior to statistical analysis, since public database and map names will now be inconsistent with the internal identifiers.

For the research laboratory not equipped for whole-genome microsatellite mapping, there are several outsourcing alternatives. However, fine-mapping of potential linkages with custom markers is almost always the next step. Outsourcing such custom genotyping is more problematic, and laboratories with serious interest in linkage mapping are encouraged to develop at least some capabilities for internal genotyping.

For microsatellite PCR, 5–20 ng of high-quality genomic DNA are required for each marker. Thus, whole-genome scans at 5-cM resolution with follow-up demand 5–20 μg of DNA per patient. These quantities can routinely be achieved using fresh blood samples in the tens of milliliters, or equivalent frozen white cells (buffy coats), or from cell culture of immortalized fibroblast lines. In cases in which a blood draw is not possible, buccal (cheek) swabs may sometimes be obtained, yielding sufficient DNA for small numbers of reactions only. Recently, several protocols have been developed for whole-genome amplification, particularly suited for whole-genome SNP analysis since so many more markers are required. The utility of these protocols for microsatellite genotyping is not fully validated.

High-volume genotype data must be appropriately archived and made available to statistical geneticists. Integrating clinical, pedigree, and genotype data sets can be surprisingly challenging. Moreover, statistical analysis programs generally require very specific formatting of data. Unfortunately, there are few appropriate commercial database prototypes serving the needs of human geneticists, although ProgenyLab is a relatively recent entry in this area. Laboratories expecting to perform large amounts of linkage mapping are highly encouraged to develop the integrated database systems.

5. Statistical genetic analysis of linkage

The essence of linkage analysis is to detect the cosegregation of a particular chromosomal segment (defined through marker genotyping) with the phenotypic state of interest, in a set of related patients such as a single family (Ott, 1991; Terwilliger and Ott, 1994). The question is whether any particular chromosome

segment in the genome cosegregates with the phenotype more frequently than one would expect by chance alone. To determine this probability usually requires elaborate mathematical analysis. The required statistical methodologies are discussed in detail elsewhere (*see* Article 50, **Gene mapping and the transition from STRPs to SNPs**, Volume 1, Article 52, **Algorithmic improvements in gene mapping**, Volume 1, and Article 17, **Linkage disequilibrium and whole-genome association studies**, Volume 3). Here, we give only the briefest overview of statistical genetics, to place the discussion of genotyping into a procedural context.

Statistical genetic tests are traditionally broadly subdivided into two main categories, those in which explicit modeling assumptions are made concerning the behavior of a presumptive causal allele and those in which no such assumptions are made. These are termed parametric (or model-based) and nonparametric (or model-free) analysis respectively. The terms "model-based" and "model-free" are preferred, however, as most methods labeled nonparametric do nonetheless rely on some genetic assumptions. In model-based analysis, assumptions are made that the disease gene–population frequency and the penetrance of the disease alleles in homozygotes and heterozygotes can be accurately estimated. When the mode of action of the disease gene cannot be predicted with confidence, such as is the case for complex diseases, model-free analyses are typically used. Generally, these simply test for excess sharing or preferential transmission of particular marker alleles in family units.

The most commonly used statistic for model-based linkage analysis is the maximum likelihood ratio. This tests the hypothesis of disease and marker cosegregation versus the null hypothesis of random segregation. For historical reasons of convenience, the base 10 logarithm of the ratio of the likelihoods is used and referred to as the LOD score (log of odds) (Morton, 1955). The conventional significance threshold used in linkage analysis is $\text{LOD} \geq 3$ for Mendelian diseases. The genome-wide significance threshold is generally set slightly higher to $\text{LOD} = 3.3$ for complex trait analysis. It is also possible to determine the significance of a test applied to a particular data set empirically using computer simulations. To this end, replicates of the family collection are generated by computer, with random genotypes based on correct inheritance, allele frequencies, and marker recombination fractions. The linkage testing procedure is conducted in each simulated dataset and the maximum LOD score or p-value is noted. The genome-wide threshold of significance is taken as a score that is exceeded in fewer than 5% of replicates.

Statistical linkage analysis can be performed using either a single genetic marker at a time (two-point linkage, that is, disease locus and marker locus), or alternatively using multiple genetic markers simultaneously (multipoint linkage). The advantage of using multiple markers is that the phase of markers can be estimated with more precision, and this can add considerable power to the test. Multipoint linkage calculations, however, require significant computational resources when sufficiently large pedigrees or numbers of markers are analyzed. Exact solutions of multipoint linkage are incomputable for very large pedigrees or marker sets with the commonly employed tools such as LINKAGE, FASTLINK, ALLEGRO, GENEHUNTER, MERLIN, and VITESSE (Lathrop *et al*., 1984; Cottingham *et al*., 1993; Schaffer *et al*., 1994; O'Connell and Weeks, 1995; Kruglyak *et al*., 1996;

Gudbjartsson *et al*., 2000; Markianos *et al*., 2001; Sobel *et al*., 2001; Abecasis *et al*., 2002). Researchers usually accept the limitations on pedigree size or number of markers, which can be examined simultaneously. There are programs such as SIMWALK, LOKI, and MCSIM that estimate inheritance vectors using approximation methods (Weeks *et al*., 1995; Heath, 1997; Thomas *et al*., 2000). Such programs have been shown to give accurate LOD scores in the majority of cases, and provide a valid alternative when exact computations are impossible (*see* Article 52, **Algorithmic improvements in gene mapping**, Volume 1).

Linkage results may be presented numerically in tabular format, but for multipoint analysis, it is common to report results graphically, with scores for parametric or nonparametric linkage plotted as a function of position on a chromosome. In this way, recombination events that unlink chromosomal segments from the phenotype appear as drops in the linkage statistic (Figure 3).

Although direct visualization of allelic phases, haplotypes, and recombination events is not theoretically necessary for locus mapping, in practice, it is widely used for manual review of linkage analysis results (Figure 4). The definition of the haplotypes in a pedigree is achieved by the phasing of alleles at each genotyped marker. By phase, we mean the two alleles of each marker must be assigned as having been transmitted from the paternal or maternal parent. For fully informative markers the process is simple, but for real markers in incompletely sampled pedigrees, phasing of alleles requires mathematical techniques. As with multipoint LOD score calculation, phase determination for large pedigrees and marker sets is computationally restrictive. An added difficulty in visualizing multimarker haplotypes is incorporating them into pedigree drawings. Pedigree

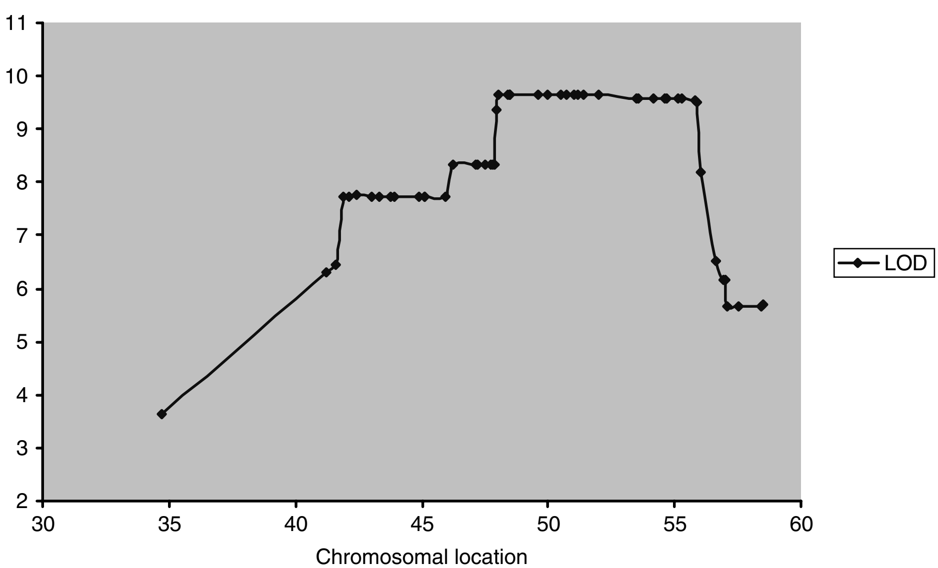

Figure 3 Multipoint linkage. mpLOD score as calculated by the MCSIM algorithm is plotted versus chromosomal location for a dense set of fine-mapping markers near the FH3 hypercholesterolemia locus (Reproduced from Timms *et al*. (2004) by permission of Springer-Verlag)

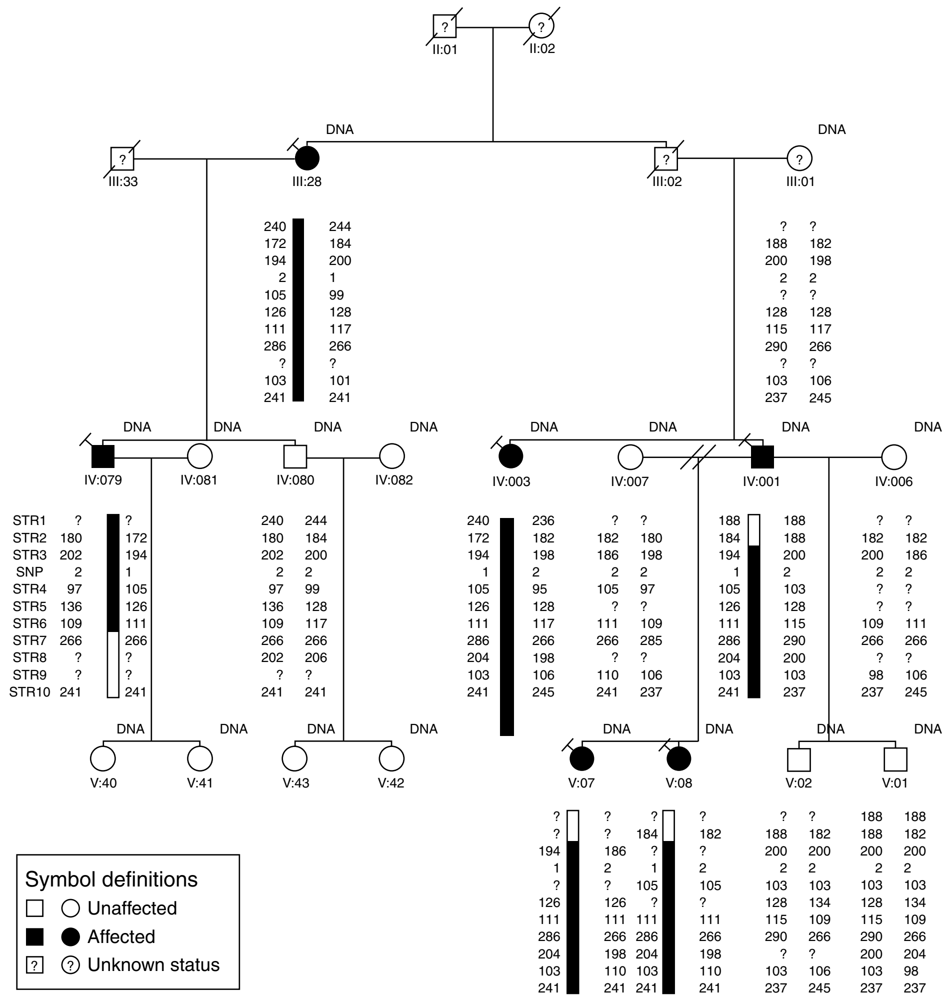

Figure 4 Haplotype visualization. A typical pedigree is shown with marker alleles phased using Genehunter. Each individual is uniquely identified by generation (in Roman numerals) and place (in Arabic numerals). Filled symbols designate affected individuals, open symbols are unaffected individuals, question marks inside symbols indicate individuals whose diagnosis is either unknown or ambiguous. Individuals with DNA samples collected are indicated. Genetic markers (anonymized) are listed in chromosomal order on the left. Beneath each genotyped individual, allele sizes are given for each marker; question marks here indicate a failure to call an allele for that marker/individual combination. Alleles have been phased so that chromosomal haplotypes may be visualized directly, although in this example only one haplotype is explicitly identified by a black bar. Recombination events may be observed in individuals IV:079 and IV:001

drawing packages such as Cyrillic, Progeny, or PedDraw are all usable, though all have limitations in dealing with large haplotypes or complex pedigrees. Haplotype reconstruction analyses can also be performed using approximation algorithms as implemented in SIMWALK or MCSIM (which must be interpreted cautiously), or else smaller pedigrees or subsections of pedigrees can be haplotyped exactly using GENEHUNTER or MERLIN and manually assembled.

As individual SNPs are insufficiently informative for most types of linkage analysis, replacement of microsatellites with SNP-based linkage mapping sets will demand multipoint linkage and haplotyping analyses. Current software packages such as Genehunter and Vitesse have not yet been extensively tested in such scenarios, however, it is anticipated that they will be applicable. New tools for SNP analysis include SNPLink, ALOHOMORA and HaploPainter (Ruschendorf and Nurnberg, 2005; Thiele and Nurnberg, 2005; Webb *et al*., 2005).

All linkage algorithms require correct Mendelian inheritance patterns of the individual marker alleles. This can be tested prior to linkage analysis using the PedCheck program, which verifies the structural integrity of the pedigrees and the Mendelian inheritance of alleles irrespective of phenotypic status (O'Connell and Weeks, 1998). When errors are detected, they may sometimes be corrected by review of the raw genotype data. However, some inheritance errors cannot be explained by any obvious technical mistakes. In such cases, it is advised to eliminate the allele calls of all pedigree members involved in the nuclear families generating the error, or in more severe cases eliminating a marker completely from analysis. One source of such inheritance errors is spontaneous mutation of a microsatellite allele to a different repeat length. Much theoretical attention has been given to the topic of unidentified genotype errors in data sets.

In monogenic as well as complex disorders, mutations in different genes can result in a similar phenotype, so that groups of families displaying a shared phenotype may not segregate a causal variant in the same gene (genetic or locus heterogeneity). Care must be taken therefore when pooling pedigrees for linkage analysis. It may be possible, in some instances, to subgroup pedigrees according to subtle phenotypic differences. Alternatively, robust statistical analyses that allow for locus heterogeneity in the calculation of heterogeneity LOD scores can be used. Those methods will improve the power of linkage detection. Alternatively, different families may segregate different mutations in the same gene for a given phenotype (allelic heterogeneity). In this case, different families will generate linkage to the same chromosomal interval although not sharing the same marker haplotype. In special cases, such as French Canada, Newfoundland, Finland, and so on, identical chromosomal segments or haplotypes can often be detected in different family units whose genealogical relationship may not be known (de la Chapelle and Wright, 1998; Laan and Paabo, 1998; Arcos-Burgos and Muenke, 2002). Such populations are frequently referred to as founder populations or population isolates.

One special subset of linkage analysis is homozygosity mapping. The general principles of recessive trait mapping are the same as for dominant traits. Accurate statistical analysis requires estimates of mutation and marker allele frequencies, which are not easily obtained in advance. However, in special cases, one can assume that affected individuals have received two copies of the same mutant allele. Such examples are common for specific populations with known high rates of consanguinity caused by either geographical or cultural factors, including founder populations (Lander and Botstein, 1987; Sheffield *et al*., 1998). Homozygous haplotype mapping can be applied by manual inspection if all affected patients from a population are homozygous for the same marker alleles for several successive markers in a genome scan. Failure to detect perfect shared marker homozygosity does not rule out the hypothesis, since recombination events may have unlinked

marker alleles from the disease allele in some affected individuals in a data set. Moreover, even in relatively isolated populations, it is possible for multiple mutations in a gene to be segregating, leading to haplotype heterogeneity and failure of homozygosity mapping. Nonetheless, this can be an extremely powerful approach.

6. Positional cloning

The ultimate purpose of linkage mapping is to define recombinant intervals sufficiently small to support direct molecular screening of DNA sequences for causal variants. It is beyond the scope of this chapter to discuss this process, positional cloning, in full detail. However, there is lively interest in significantly reducing the cost of DNA sequencing, and it is not impossible that something like a large scale gene-screening approach could become cost-effective within the next few decades, which in theory could obviate the need for mapping (*see* Article 7, **Single molecule array-based sequencing**, Volume 3).

One can approximate the LOD score equivalent to a given interval size with the formula: size in cM = 60/LOD, such that a LOD score of 3.0 is on average equivalent to an interval of 20 cM (Sham, 1998). Even in the case of a monogenic disorder, with a well-defined chromosomal locus and constrained recombinant boundaries, it has historically been a significant challenge to identify causal variants. With the advent of the human-genome project, in the best case laboratories can simply resequence annotated genes within an interval (*see* Article 23, **The technology tour de force of the Human Genome Project**, Volume 3 and Article 24, **The Human Genome Project**, Volume 3). More typically, time and resources must still be devoted to clarifying gene content. Novel genes and new exons of incompletely defined gene transcripts, still arise at a significant rate in positional cloning projects, although this should become less of an issue within the next several years.

There are numerous approaches to mutation detection. Ultimately, the gold standard remains direct DNA sequencing, but several other physicochemical techniques (denaturing HPLC, mismatch scanning, chip-based resequencing, etc.) have been developed as alternatives for first-pass analysis. This remains a fast-moving field with technical improvements ongoing. Even for direct sequencing, software tools for more highly automated detection of sequence variants are still in development (Polyphred, Sequencher, Staden Tracediff, Softgenetics MutationSurveyor, etc.).

For linkage-based positional cloning, rare variants, typically resulting in obvious changes in gene function (frameshifts, stop codons, missense changes in conserved or biochemically validated amino acid residues, changes in conserved splice junction elements, etc.), are generally well accepted as causal for rare phenotypes especially when they are absent or at vanishing small frequencies in the general population (usually such a mutation is defined as undetected in at least 100 random control individuals). The overall mutation rate in the general population is such that for severe loss-of-function mutations there are usually many different allelic mutations detected for the same phenotype. Once a positional cloning project

has led to provisional identification of a small number of mutations, follow-up validation of new mutations in additional patients often ensues rapidly. In the cases where phenotypes are proposed to arise from unusual types of mutations, such as specific gain-of-function changes, validation may be more challenging.

7. Future of linkage mapping

We believe that linkage mapping still plays an important role in disease gene identification. Of the proposed 25–30 000 human genes (Jaillon *et al*., 2004), fewer than 2000 have identified genetic variants associated with a clear phenotype in the OMIM database. For discovering the phenotypic effects of mutation in the remaining genes, especially for high penetrance mutations such as severe loss-of-function, traditional family-based linkage analysis is still the most efficient technology available. Homozygosity mapping of recessive phenotypes in appropriate populations, through a hybrid linkage/LD approach, can be even more efficient in the gene discovery process.

8. Electronic databases

These indicate some of the most commonly used sites for sources of genetic and genomic data and services.

Short Specialist Review

Microarray comparative genome hybridization

Robert A. Holt and Martin Krzywinski
Canada's Michael Smith Genome Sciences Centre, Vancouver, BC, Canada

1. Introduction and history

Comparative genome hybridization (CGH) is a method for genome-wide detection of chromosomal differences (*see* Article 11, **Human cytogenetics and human chromosome abnormalities**, Volume 1) between a sample and control that are due to DNA copy number changes. Briefly, total genomic DNA from a "test" and a "reference" individual are labeled with different fluorescent dyes and cohybridized to a representation of the genome in the presence of CoT-1 DNA (At a given temperature, the rate of DNA renaturation depends on concentration (Co) and time (t). CoT-1 DNA represents a rapidly reassociating and thus a highly repeat-enriched fraction of genomic DNA. It is typically derived by denaturing sheared gDNA at a concentration of 3 mM, reassociating for 5.5 min, and then isolating the reassociated double-stranded product.), which is used to block repetitive sequence. The ratio of signals emitted from different loci provides a map of variation in copy number in the genome of the "test" individual. Originally, metaphase chromosome spreads were used as the genome representation (Kallioniemi *et al*., 1992) for CGH, and in this format the technique has been widely used (Nacheva *et al*., 1998; Brown and Botstein, 1999; James, 1999; Weiss *et al*., 1999; Ness *et al*., 2002; Albertson and Pinkel, 2003) for the analysis of tumors (*see* Article 14, **Acquired chromosome abnormalities: the cytogenetics of cancer**, Volume 1) and developmental abnormalities such as mental retardation and congenital anomalies. A number of experimental and analytical modifications (*see* Article 58, **CGH data analysis**, Volume 7) have been proposed to increase the resolution, such as standard reference intervals (Kirchhoff *et al*., 1999), and precision, such as four-color CGH (Karhu *et al*., 1999). Microarray comparative genome hybridization (maCGH) represents an evolution of the classical method, whereby chromosome spreads are replaced by DNA fragments of known genomic location spotted on a microarray slide. There are several variations of the maCGH format, in which either BACs (Bacterial Artificial Chromosomes), cDNAs, or oligonucleotides are used as the DNA target. Regardless of format, maCGH offers distinct advantages over both classical CGH and other microscopic cytogenetic methods. The resolving power of maCGH is considerably greater than the maximum of approximately

5 Mb achievable by G-banding (*see* Article 12, **The visualization of chromosomes**, Volume 1) or 1–2 Mb (amplifications) and 10 Mb (deletions) by conventional CGH (Bentz *et al*., 1998; Kirchhoff *et al*., 1999). The only theoretical limits on resolution are the number, size, and sampling density of the targets on the array. Further, the method is more scalable than microscopic methods, allowing the parallel and quantitative (Moore *et al*., 1997; Kirchhoff *et al*., 1998; Quackenbush, 2002; Geller *et al*., 2003) evaluation of large numbers of samples, and does not require intact chromosomes for analysis. The most significant limitations of maCGH are (1) the genomic location of amplified DNA sequence is not known and (2) unless chromosomes are first separated by flow cytometry then labeled and hybridized individually (a process called array painting (Fiegler *et al*., 2003a)), the assay is blind to chromosomal aberrations that do not result in copy number changes, such as balanced translocations. Nonetheless, maCGH has proven its utility through the detection of DNA copy number changes in tumors (Albertson *et al*., 2000; Bruder *et al*., 2001; Struski *et al*., 2002; Nakao *et al*., 2004; Cai *et al*., 2001; Zhao *et al*., 2004), children with mental retardation and various dysmorphic syndromes (Shaw-Smith *et al*., 2004; Veltman *et al*., 2002; Xu and Chen, 2003; Yu *et al*., 1997), and molecular evolution (Locke *et al*., 2003).

2. BAC arrays

Presently, the construction of genomic microarrays is dominated by the use of BACs as the target for hybridization. Several of the BAC libraries that provided critical positional information for guiding sequencing and assembly of the human genome (Lander *et al*., 2001; Venter *et al*., 2001) are available for array construction. Initial use of these resources provided first-generation arrays with approximately 1-Mb resolution (Snijders *et al*., 2001; Fiegler *et al*., 2003b). Recently, an optimal tiling set of clones providing coverage for the entire genome has been selected (Krzywinski *et al*., 2004) and a high-resolution BAC microarray has been manufactured using these clones (Ishkanian *et al*., 2004). Theoretical resolution of this clone set is based on the degree of clone overlap, and is calculated to be 75 kb.

BACs are desirable as hybridization targets not only because their genomic positions are known accurately but also because their large insert size (approximately 150–200 kb on average) allows integration of hybridization signal over a comparatively large region and gives sufficient sensitivity to routinely detect single copy number changes starting with only a few hundred nanograms of labeled test DNA (Albertson and Pinkel, 2003). Preparation and spotting of BACs on to arrays is made difficult by the low yield of DNA from BAC cultures and the large molecular weight of the DNA. Both factors are a detriment to handling DNA at the high concentration necessary for achieving good signal-to-noise ratio in hybridizations. These problems have been overcome by preparing a representation of each BAC clone by ligation-mediated PCR (LMPCR), whereby clones are fragmented, oligonucleotide adapters are ligated to the ends of fragments, and the fragments are amplified by PCR using adapter-specific primers. In this manner, a large and renewable quantity of DNA suitable for array printing is generated. LMPCR was the first reported technique for the preparation of clones for maCGH

and ratio data obtained from arrays composed of LMPCR BAC representations have been shown to be essentially identical to ratios reported on intact DNA from the same BACs (Pinkel *et al*., 1998). Degenerate oligo primed PCR (DOP-PCR) (Fiegler *et al*., 2003b) and rolling circle amplification (RCA) (Smirnov *et al*., 2004; Buckley *et al*., 2002) have also been successfully used in the preparation of BAC DNA for spotting. The principal drawbacks of BAC arrays include the ultimate limit of resolution determined by their large insert size and the continued necessity for using large amounts of CoT-1 DNA to block highly repetitive sequences (although numerical methods exist to mitigate this effect (Kirchhoff *et al*., 1997)). Further complications from repeat elements arise in telomeric and pericentromeric regions. While these regions often contain loci of interest, they are highly repetitive and therefore masked by CoT-1 DNA. Care must also be taken to avoid being misled by low-copy-repeat elements that are not masked by CoT-1 DNA. It is estimated that 5% of the human genome is made up of interspersed duplications (*see* Article 26, **Segmental duplications and the human genome**, Volume 3) (Eichler, 2001; Bailey *et al*., 2002) that represent, for example, homology between gene families, and these naturally occurring duplications can confound analysis of BAC maCGH data.

3. cDNA arrays

The use of cDNA clones as the target for hybridization in maCGH (Pollack *et al*., 1999; Kargul *et al*., 2001; VanBuren *et al*., 2002; Yamamoto *et al*., 2002) has obvious advantages in terms of the number and variety of clone sets and prefabricated arrays available for human studies, but also for studies of other model organisms, pathogens, disease vectors, novel therapeutics, and organisms of industrial importance for which no genome sequence or validated large insert genomic clone set is yet available. While CGH using cDNA arrays is informative only for coding sequence, concentrating resolving power on this fraction of the genome can be considered an advantage, particularly when gDNA and RNA are available from the same individual, allowing cointerrogation of gene dosage and gene expression at precisely the same loci. Information on copy number changes in gene regulatory regions or other nontranscribed regions may be missed, but the same is true for some of the current generation BAC arrays that do not offer complete genome coverage. The principal drawback in using cDNA clones as hybridization targets is limited sensitivity. Relatively large amounts of labeled DNA (up to 10 μg) are required for each hybridization and the resulting signal must be averaged over a number of clones to define local copy number (Pollack *et al*., 1999). While large genomic amplifications are readily detectable, cDNA arrays are generally not considered to be the best tool for detection of single copy number differences.

4. Oligonucleotide arrays

Two recent developments in the application of oligonucleotide arrays (*see* Article 57, **Low-level analysis of oligonucleotide expression arrays**, Volume 7) to DNA copy

number analysis have shown promise: representational oligonucleotide microarray analysis (ROMA) (Lucito *et al*., 2003; Sebat *et al*., 2004) and the use of Affymetrix SNP chips. ROMA is an interesting approach enabled entirely by completion of the reference human genome sequence. In ROMA, a representation of the genome sequence is prepared by digesting gDNA with a restriction enzyme (BglII) and fragments are amplified using the same basic procedure as LMPCR, described above. ROMA arrays are spotted with oligonucleotides (70mers) that are designated to have near-homogeneous annealing characteristics, and match unique (nonrepetitive) sequence present within computationally defined BglII fragments. Thus, the target sequence on the array is repeat-free, obviating the need for CoT-1 DNA as a blocking agent. The reduced complexity of the target and probe fractions improves signal-to-noise performance and reduces the amount of sample required for hybridization. In principle, the resolution is very high, but in practice a finite number (approximately 120 000) of repeat-free BglII fragment 70mers in the human genome places an upper limit on resolution. Resolution could be increased further, in theory, by digesting with more than one restriction enzyme, and in time, different restriction enzymes and enzyme combinations will likely be found that give an optimal number and spacing of targets. An 85 000-element ROMA array has been characterized (Lucito *et al*., 2003) and has been shown to be capable of detecting both known and novel single and multiple copy deletions and amplifications, including several less than 100 kb in length. The practice of ROMA is restricted to organisms that have a quality whole-genome sequence available, and the array design steps are demanding, but this approach holds much promise.

Single nucleotide polymorphism (SNP) (*see* Article 71, **SNPs and human history**, Volume 4) have recently been developed by Affymetrix for array-based genotyping (Kennedy *et al*., 2003), and these arrays have also shown some promise as a platform for evaluation of DNA copy number (Zhao *et al*., 2004; Bignell *et al*., 2004). These arrays contain allele-specific 25mer oligonucleotide probes complementary to SNPs predicted to be in the fraction of the genome represented by the digestion fragments generated by the enzyme used in sample preparation (typically Xba1 or HindIII). Current arrays formats contain up to 100 000 SNPs and provide resolution as low as approximately 30 kb. Multiple different oligonucleotide probes cover each polymorphic site on both the sense and antisense strand. Like ROMA, preparation of sample DNA for hybridization relies on LMPCR for sample complexity reduction and amplification, the difference being that for the Affymetrix experiments, XbaI or HindIII, rather than BglII, is the enzyme used for digestion of sample gDNA. It is important to note that the use of SNP arrays for DNA copy number evaluation is fundamentally different from ROMA, BAC or cDNA maCGH in two regards. First, the SNP chip assay does not rely on comparative hybridization. Rather, each sample DNA is individually labeled and hybridized. Copy number differences are detectable only in comparison to reference DNA samples evaluated in separate experiments and stored in a database provided by Affymetrix. Second, because alleles are present as separate array elements, the SNP chip platform uniquely enables loss of heterozygosity events that are caused by hemizygous deletion to be distinguished from those that are caused by copy number neutral events, such as deletion followed by subsequent duplication of the remaining locus. Loss of heterozygosity (LOH) is common in cancer cells (Vogelstein and

Kinzler, 1998), where many tumor suppressor genes are inactivated by mutation in one allele and hemizygous deletion of the other wild-type allele. However, other LOH mechanisms such as mitotic recombination or gene conversion do not lead to copy number changes, and it is important to be able to distinguish between these mechanisms. Further, genetic deletion syndromes such as Angelman's syndrome have different outcomes depending on whether the deleted allele is maternally or paternally inherited. Thus, the ability to distinguish parent-of-origin effects has implications for genetic diagnosis and counseling.

The present Affymetrix SNP chips detect homozygous deletions, hemizygous deletions, and amplifications simultaneously with LOH detection (Zhao *et al*., 2004; Bignell *et al*., 2004). Direct comparison with BAC and cDNA array analysis (Zhao *et al*., 2004) showed that the three platforms gave generally comparable copy number results, although the noise of individual measurements was greater on the SNP chip platform, and analysis of raw data using a Hidden Markov Model (*see* Article 98, **Hidden Markov models and neural networks**, Volume 8) was necessary to obtain the best inference of copy number. As with ROMA, high target density is possible with this approach, and a 100 000-element XbaI-based SNP array is presently under construction, which will likely prove to be a very powerful and useful tool.

5. Experimental considerations

While the platforms described above (BAC CGH, cDNA CGH, ROMA, Affymetrix SNP chips) have all been shown to have utility in evaluation of DNA copy number, there are several additional issues to be considered when investigating DNA copy number aberrations. These include the amount, integrity and source of sample and reference DNA, the sensitivity of the assay, and the prevalence of copy number polymorphisms. Regarding input sample and reference DNA, BAC array CGH and the ROMA-based methods require several hundred nanograms of genomic DNA per hybridization, and cDNA arrays require considerably more. While several hundred micrograms of DNA seem a modest amount, even this quantity can be difficult to obtain from clinical samples, particularly from microdissected tissue, or from postmortem tissue where DNA may have degraded. Regarding reference DNA, it is desirable, if not essential, to use the same reference DNA within a series of hybridizations from the same study, or to compare across studies. Thus, there is a need for a large repository of reference DNA in laboratories performing this assay. Ideally, this would be constitutional DNA from a single donor with a defined karyotype, but because this is impractical, pooled DNA from multiple individuals of the same gender (available commercially form Clontech or Novagen) is often used as reference. With sufficient numbers of individuals represented in a DNA pool, any individual karyotypic anomalies become negligible. While in principle DNA from selected cell lines would offer a renewable source of reference DNA, the prevalence of karyotypic anomalies in immortalized cells may make results difficult to interpret, and caution is advised. Of note, recent success in amplifying sample and reference DNA using Phi29 polymerase or Bst polymerase suggests that this approach may provide a practical solution where input DNA is

limiting for CGH experiments. Initial results show limited representational bias and background amplification if experimental conditions are carefully controlled (Lage *et al*., 2003). Even with appropriate input sample and reference DNA, a common observation is that maCGH generally does not achieve theoretical values for copy number differences (Albertson and Pinkel, 2003). For example, female test versus male reference comparisons typically give less than the expected 3:2 ratio for X-chromosome probes and measurable signal for the presumably absent Y chromosome. The reasons for dynamic range suppression are poorly understood, but may relate to the presence of somatic mosaicism (*see* Article 18, **Mosaicism**, Volume 1) (as in the case of tumor samples contaminated with surrounding stromal cells of normal karyotype) or, for clone-based arrays, deletion or insertion events that span less than the length of the target cDNA or BAC. Incomplete suppression of repetitive sequence may also be implicated. It is for these reasons that independent verification of all putative copy number changes by a second method such as FISH (*see* Article 22, **FISH**, Volume 1) or quantitative real-time PCR remains essential.

Copy number polymorphisms (CNPs) have the potential to confound CGH analysis. While there are only a small number of well documented CNPs in the human population, such as the Rh locus (Wagner and Flegel, 2000), the CYP2D6 locus (Meyer and Zanger, 1997), and the green color pigment locus (Nathans *et al*., 1986), as maCGH becomes broadly applied it is becoming clear that CNPs are not uncommon, and represent an important source of genetic variation (Sebat *et al*., 2004; Iafrate *et al*., 2004). DNA copy number variation is clearly a hallmark of tumor cells (Vogelstein and Kinzler, 1998), and there is also evidence that substantial levels of chromosomal anueploidy may exist in neurons (Rehen *et al*., 2001). Because many or perhaps most CNPs may be benign, a survey of common polymorphisms in different ethnic populations would provide a valuable resource for interpreting disease-focused CGH studies. Presently, however, owing to the unknown scope of copy number polymorphism, it is important that studies investigating CNP disease associations include an appropriate group of matched control individuals.

Short Specialist Review

Linkage disequilibrium and whole-genome association studies

Karen L. Novik and Angela R. Brooks-Wilson
Genome Sciences Centre, Vancouver, BC, Canada

1. Introduction

Complex diseases are those that involve multiple genetic loci as well as environmental or lifestyle effects (*see* Article 57, **Genetics of complex diseases: lessons from type 2 diabetes**, Volume 2). Such diseases often affect a substantial proportion of the population. Uncovering the genetic components of such diseases is a current challenge for human genetics.

2. Complex diseases and association studies

As an example, let us consider the situation for one complex disease, breast cancer. It has been estimated that less than 2% of all breast cancer cases are caused by rare inherited mutations in two genes called *BRCA1* and *BRCA2* and that these genes account for only 20% of the excess familial risk of the disease (Anglian Breast Cancer Study Group, 2000). Clearly, other breast cancer susceptibility genes remain to be identified, especially for the sporadic form of the disease that is rarely the result of mutations in the *BRCA* genes (Gayther *et al*., 1998). Segregation analysis suggests that there could be many different breast cancer loci, each contributing a small effect (Antoniou *et al*., 2001).

The association study is a recent method that can be used to identify complex disease genes (for review see Cardon and Bell, 2001). This method compares the frequency of genetic variants in unrelated cases (who have a given disease) and controls (who are free of disease) to identify variants or regions that are putatively involved in disease etiology. If such variants are *associated* with disease, further characterization is necessary to demonstrate a causal role in the disease process. Association studies can use a candidate gene approach to investigate polygenic disorders; the choice of candidates is based on previous biological and/or genetic insights into that disease. BRCA1 and BRCA2 for example, have roles in mammalian DNA double-strand break (DSB) repair, and this has provided a rationale for breast cancer association studies that have focused on numerous members of this molecular pathway. Variants and/or haplotypes of BRCA2,

XRCC2, XRCC3, and Ligase 4 have all been associated with modest risks of breast cancer and population-attributable risks (the proportion of a population's breast cancer that is due to a particular genetic variant) of up to 2% (Healey *et al*., 2000; Kushel *et al*., 2002). Although candidate gene approaches have successfully identified low-risk variants for breast cancer susceptibility, this approach is only just beginning to address the genetics of this complex disease.

3. Whole-genome association and linkage disequilibrium

Whole-genome association studies, in contrast to candidate gene–based studies, do not require existing knowledge of the relevance of specific genes, pathways, or biological hypotheses in order to identify the genetic determinants of disease. Whole-genome scans use genetic markers of at least moderate allele frequency distributed across the genome. There are currently 5 million validated SNPs distributed across the 3 billion base pairs of human sequence (single-nucleotide polymorphism database – dbSNP build 123 – **www.ncbi.nlm.nih.gov/SNP**), and directed resequencing efforts show that more SNPs exist than are currently in the public domain (Carlson *et al*., 2003). Is it necessary to include all of this genetic variation in a whole-genome scan for genetic association? Fortunately, the genetic phenomenon of linkage disequilibrium (LD) reduces the number of variants necessary for a whole-genome association study. LD, otherwise known as nonrandom association of alleles, can be used to correlate genetic variation with phenotypic traits (*see* Article 73, **Creating LD maps of the genome**, Volume 4). LD between alleles of physically linked markers is an indication of their recombination history in the population, and can be affected by numerous contributing factors such as recombination rate, mutation age, genetic drift, ethnic diversity and natural selection. LD can vary significantly within and between different populations, in particular, Europeans show greater LD than African populations (for review, see Ardlie *et al*., 2002). Furthermore, LD varies between and across whole chromosomes (Reich *et al*., 2001; Patil *et al*., 2001; Dawson *et al*., 2002). Many studies suggest that the human genome is organized into haplotype blocks that show high LD, interspersed with shorter regions of high recombination and consequently low LD (Gabriel *et al*., 2002; Ardlie *et al*., 2002 and references therein). Certainly, chromosomes 21 and 22 both show this blocklike LD structure (Patil *et al*., 2001; Dawson *et al*., 2002). Common haplotypes can represent most of the genetic variation across relatively large regions of the genome. These haplotypes (including the known and unknown variation) can be genotyped by using a small number of "haplotype tagging" SNPs (htSNPS) that suffice to specify all reasonably common haplotypes in the population of interest (*see* Article 12, **Haplotype mapping**, Volume 3). Thus, LD, in the form of haplotypes, can be used to reduce the number of SNPs needed to genotype a particular genomic region or the entire genome. An international collaborative effort, the HapMap project, is underway to determine the size and boundaries of the human haplotype blocks. This project is now midway through the typing of 600 000 SNPs (on average 1 every 5000 bp) in each of the three populations (International HapMap Consortium, 2003; Couzin, 2004). It has already become clear that this number of SNPs will be insufficient to produce a refined haplotype map representative of all populations (Gabriel *et al*., 2002).

The number of markers necessary to conduct a whole-genome scan for association will be a function of the average size of a haplotype block in the human genome and the number of markers necessary per block to specify all reasonably common haplotypes in populations of interest. Estimates of the number of markers required range from 100 000 to 1 million SNPs (Gabriel *et al*., 2002; International HapMap Consortium, 2003; Carlson *et al*., 2003). Until the completion of the HapMap, the best current prediction of the average size of an LD block for European populations is in the range of 10–30 kb; blocks in African populations are generally smaller (Gabriel *et al*., 2002; Ardlie *et al*., 2002 and references therein). The feasibility of whole-genome scanning for association will also depend upon the lower limit of odds ratio (OR) that is desirable to identify for a given disorder. Major genetic effects can be detected using smaller case/control groups; subtle effects such as a doubling of risk (OR = 2) require larger sample sizes. The sample size used for a study thus determines whether it will simply skim off the larger genetic effects, neglecting smaller ones, or whether it will be a more thorough assessment of the genome in terms of both major and subtle genetic risk factors. The optimal sample size required for a meaningful whole-genome scan is also impacted by statistical corrections required to adjust for multiple testing.

4. Gene-environment interactions

A more comprehensive understanding of the causes of complex diseases will also depend on studies that incorporate gene-environment interaction. Such studies require both accurate environmental and/or lifestyle data for the same group of individuals that are characterized genetically, thus necessitating even larger sample sizes than purely genetic studies. The sample sizes of association studies are limited by issues such as the cost of phenotypic characterization of cases and controls for a given disorder, which can vary greatly between diseases.

5. Technology and cost

For whole-genome scans for association, cost will be a key consideration. Let us assume that a comprehensive genome scan is likely to involve approximately 500 000 markers and that such an experiment will include at least 1000 samples. The number of genotypes required is hence on the order of 5×10^8 genotypes. If costs were only 1 cent per genotype (this has yet to be achieved routinely), the hypothetical genome scan above would cost $5 million to complete. This figure is unrealistic for all but the largest research groups and, therefore, the per-genotype costs would have to be reduced severalfold to fit into the budgets of most laboratories.

The high cost of genome scanning could be decreased by two means, (1) the use of DNA pools rather than individual samples and (2) the use of very high orders of multiplexing or parallel genotyping of SNPs in individual DNA samples (*see* Article 77, **Genotyping technology: the present and the future**, Volume 4). DNA pooling involves the mixing of precisely equal quantities of individual DNAs to form, for example, “case” and “control” pools, followed by a genotyping procedure

that can determine the allele frequency of each pool at each SNP tested. For analysis of DNA pools, the genotyping procedure used must be quantitative and as sensitive as possible. For complex diseases, it is likely that large numbers of genetic factors, many with subtle effects, will combine to produce disease susceptibility. Genotyping methods that are not sufficiently quantitative or sensitive to detect small differences in allele frequencies between pools would likely be inadequate to dissect many of the genetic factors underlying common complex diseases. To date, few methodologies have been shown, in peer-reviewed publications, to be truly quantitative. Two such methods are the MassARRAY system (Sequenom, Inc.) and pyrosequencing (Biotage AB), which have been shown to quantitatively measure differences in allele frequencies below 2% (Bansal *et al*., 2002; Herbon *et al*., 2003; Gruber *et al*., 2002). While pooling offers a reduction in the number of DNAs to be genotyped, some information is also lost, as differences within a pool can no longer be analyzed. In particular, it is less powerful than individual genotyping when known risk factors (such as smoking, age, sex) are being considered for each sample (Carlson *et al*., 2004). One way to counter this loss is to sort the samples into subpools on the basis of their respective risk factors. This will, however, increase the number of assays per marker, which is contrary to the rationale for pooling in the first instance (Carlson *et al*., 2004). Working from our earlier assumption of 500 000 markers and 1000 samples, a genome scan involving two DNA pools, analyzed in triplicate, would need to have a pool-genotype cost of $0.33 or less to give a total cost of $1 million (corresponding to a fivefold overall reduction in cost compared to individual sample genotyping). In addition, such technologies would need to be accompanied by a ready set of assays corresponding to a suitably dense series of markers.

Other technology developers have focused on highly parallel or highly multiplexed genotyping of individual samples using techniques that need not be precisely quantitative, but are capable of reliably distinguishing heterozygotes. Such technologies include capillary electrophoresis-based methods such as the Applied Biosystem SNPlex™ system (48-plex), the Illumina BeadArray (1536-plex) and chip array-based methods such as those of ParAllele (10 000 nonsynonymous SNPs), Affymetrix (currently 100 000 SNPs per chip), or Perlegen (up to 1.5 million SNPs). Under our assumption of 500 000 SNPs and 1000 samples, the cost of genotyping individual samples using these methods would need to be approximately 0.2 cents per genotype to bring the cost of such a study to $1 million and be attractive to a wide variety of laboratories. The cost of several high-throughput methods is now on the order of cents per genotype (*see* Article 77, **Genotyping technology: the present and the future**, Volume 4). Until this is reduced further, however, whole-genome scans for association will remain in the domain of an exclusive few laboratories or companies with the resources to cover the current costs.

6. What is the current status of human genome scans?

Various corporate groups refer to unpublished genome scans for association. Academic groups, in contrast, have published several papers reporting "genome scans"

for association using only a few thousand markers that are clearly inadequate in number to be considered a representative of the entire human genome. While both types of report represent some progress, it seems that genome scans for association at the present time remain unproven.

In the meantime, as the HapMap moves toward completion and commercial groups vie aggressively to produce faster and cheaper genotyping methods, academic researchers continue to carry out hypothesis-driven candidate gene studies; basing their intelligent guesses on the current understanding of human disease biology. In the future, comparing these results to those of whole-genome scans for association may tell us how much – or how little – we understand about our own genome.

Short Specialist Review

Fingerprint mapping

Jacqueline E. Schein and Martin I. Krzywinski
Genome Sciences Centre, British Columbia Cancer Agency, Vancouver, BC, Canada

1. Introduction

Physical maps constructed from fingerprinted clones have been widely used in genomic research, for both genome-wide and region-specific analyses. As with other clone-based physical map construction strategies, one starts with a library of randomly arrayed clones, each clone containing an unknown fragment of DNA derived from the genome of interest, and identifies experimentally clone relationships that describe their proximity to one another in the intact genome. On the basis of these established relationships, an ordered set of overlapping clones representing the underlying genome is generated. In fingerprint map construction, these clone relationships are determined by comparing the characteristic patterns of DNA fragments generated by restriction digests of the cloned DNA (the clone "fingerprint"). Any two clones sharing a large fraction of their DNA are expected to have very similar fingerprint patterns. Therefore, by comparing the similarity of fingerprint patterns of all clones within a set of fingerprinted clones, those with significant similarity can be inferred as being derived from DNA from overlapping segments of the genome. The number and pattern of shared restriction fragments allows the clones to be ordered with respect to each other, thereby reconstructing contiguous regions of the genome. Because they are clone based, these maps provide a sequence-ready resource for genome sequencing efforts (*see* Article 8, **Genome maps and their use in sequence assembly**, Volume 7) and an entry point for cloning and functional analysis of genes of interest. They represent and elucidate the underlying structure of the genome being studied and can be integrated with other genomic and genetic data, such as genetic markers and genomic or gene-based sequences, allowing correlation with whole-genome sequence assemblies as well as other types of genome maps, including cytogenetic maps, genetic linkage maps (*see* Article 15, **Linkage mapping**, Volume 3), radiation hybrid (RH) maps (*see* Article 14, **The construction and use of radiation hybrid maps in genomic research**, Volume 3), and sequence tag site (STS) maps (*see* Article 13, **YAC-STS content mapping**, Volume 3). For an overview of genome mapping, see Article 9, **Genome mapping overview**, Volume 3. The specific details of fingerprint map construction will be discussed here, beginning with a description of how this approach to physical mapping evolved.

2. Origins of fingerprint mapping

2.1. Molecular tools derived from basic research

Fingerprint mapping is the determination of the relative positions of restriction endonuclease sites along a DNA molecule. The concept of restriction mapping is therefore by definition contingent on the existence of restriction endonucleases. Thus, a critical step in the evolution of this mapping technique was the discovery, isolation and characterization of these enzymes. Evidence of the existence of restriction enzymes was first observed in the early 1950s through the phenomenon of host-controlled variation, in which the ability of bacterial viruses to reproduce in certain host strains was dependent upon the host in which they had previously reproduced. This mechanism of host specificity in *Escherichia coli* was found to involve both DNA modification and DNA restriction activities. In 1968, a restriction enzyme from *E. coli K*, active against λ DNA, was the first restriction endonuclease to be highly purified and characterized. Purification and characterization of additional restriction enzymes rapidly followed (for early reviews, see Meselson *et al*., 1972; Nathans and Smith, 1975).

The potential of using restriction endonuclease digestion to characterize genomic DNA was first demonstrated in the early 1970s on SV40 DNA and the replicative form of ϕX174. These studies showed that specific viral DNA cleavage products could be generated by endonuclease digestion, that these products could be separated by polyacrylamide gel electrophoresis and individually identified, and that the number and size of the fragments produced could be used to characterize the viral DNA. The rationale behind these DNA cleavage experiments was twofold; (1) specific fragmentation of viral DNA chromosomes could potentially be used to generate small, unique DNA fragments that would be amenable to sequencing and (2) if such specific fragments could be produced, then the potential existed to order them with respect to each other and therefore provide a framework (i.e., a physical map) on which to map the location of specific genetic functions in the viral DNA. Indeed, several known ϕX174 activities had been successfully mapped to specific restriction fragments identified in the initial cleavage study. The DNA fragment patterns derived from restriction endonuclease digestion and electorphoretic separation (i.e., the fingerprint) were additionally found to be sufficiently sensitive and reproducible that they could be used to distinguish between different strains of SV40 (Nathans and Danna, 1972), in what may possibly be the first comparative genome mapping experiment.

The first genome restriction map was generated for the SV40 genome (Danna *et al*., 1973), using partial DNA digestion with restriction endonuclease isolated from *Haemophilus influenzae* and subsequent complete digestion of the partial digest products with two additional restriction endonucleases. This resulted in a circular map composed of the relative positions of the cleavage sites within the DNA molecule. Using similar techniques, restriction maps for the genomes of a number of other small DNA viruses were also constructed, including those of the polyoma virus, λ, øX174, and adenovirus. A simple method for fragment separation on agarose gels and visualization using ethidium bromide was also developed during this time (Sharp *et al*., 1973). Restriction mapping of DNA molecules became

a standard method for the direct characterization of small DNA chromosomes. The fundamental reagents and techniques required for fingerprint mapping had thus been established, using in part molecular tools that had been developed as a result of unrelated research into the mechanisms underlying bacterial host–pathogen interactions.

2.2. From viruses to humans: fingerprinting large genomes

The large size of bacterial and eukaryotic chromosomes, and the number and size of restriction digest fragments generated from these larger DNA molecules, made direct application of the restriction mapping techniques developed for the smaller viral DNA genomes problematic. Two primary technological advances provided the means to fingerprint map these large DNA molecules; the development of pulsed-field gel electrophoresis (PFGE) (Schwartz and Cantor, 1984) for the separation of large DNA fragments, and the development of recombinant DNA technology (Jackson *et al*., 1972; Cohen *et al*., 1973) to reduce large segments of genomic DNA into a number of smaller, more easily manipulated cloned genomic fragments.

These technologies led to the development of two approaches to fingerprint map large regions of DNA. In one method, described as a "top-down" or landmark mapping approach, intact genomic DNA (i.e., a whole chromosome) was digested with enzymes that cut rarely in the genome, generating large DNA fragments that were then separated by size on agarose gels by PFGE. These fragments were typically mapped relative to each other by hybridization of DNA probes, such as gene-based sequences or probes specific for restriction fragment ends. Because these restriction endonuclease recognition sites occur infrequently within the DNA sequence, this fingerprinting method generates a long-range but low-resolution "macrorestriction" map of the genome. Restriction maps for the genomes of *E. coli* (Smith *et al*., 1987), *Saccharomyces cerevisiae* (Link and Olson, 1991), and *Schizosaccharomyces pombe* (Fan *et al*., 1989) were generated using this approach. However, since this method requires the isolation of intact chromosomal DNA and the separation and detection of all fragments generated from a restriction digest of this DNA, it was not particularly well suited to the mapping of larger eukaryotic genomes. Additionally, it did not provide reagents that could be readily applied to functional studies or to sequencing strategies.

The second method utilized a "bottom-up" approach, in which many copies of the genome were first fragmented into smaller pieces of DNA, cloned into a bacterial vector and propagated in a suitable bacterial host. These smaller DNA fragments were easily isolated with standard molecular procedures and were amenable to restriction fingerprinting using the same general techniques applied to the viral DNA genomes. Thus, the restriction fingerprinting task was transformed from application to an entire eukaryotic chromosome to that of a series of easily manipulated DNA fragments. This approach was therefore more suited in terms of high-throughput laboratory techniques than the top-down approach, with the additional benefit of providing higher resolution due to the increased density with which restriction sites could be sampled along the DNA. It does, however, represent a

more complex task in terms of assembling a global fingerprint map from the individually fingerprinted DNAs (*see* Article 19, **Restriction fragment fingerprinting software**, Volume 3 and Article 1, **Contig mapping and analysis**, Volume 7). A variety of different strategies employing this basic approach have been used to construct fingerprint maps for eukaryotic genomes. The application of this methodology to the construction of whole-genome fingerprint maps was pioneered in the model organisms *Caenorhabditis elegans* (Coulson *et al*., 1986) and *S. cerevisiae* (Olson *et al*., 1986). The approach was soon employed in the generation of maps for other model organisms, including those of *E. coli* (Kohara *et al*., 1987; Knott *et al*., 1989), *Arabidopsis thaliana* (Hauge *et al*., 1991; Marra *et al*., 1999), and *Drosophila melanogaster* (Siden-Kiamos *et al*., 1990; Hoskins *et al*., 2000). Large regions of human chromosomes were also mapped with a variation of this approach (Carrano *et al*., 1989; Marra *et al*., 1997). Ultimately, as the molecular and computational techniques employed in random-clone fingerprinting and map assembly matured, a clone-based fingerprint map for the entire human genome was achieved (McPherson *et al*., 2001). Fingerprinted clone maps have been constructed for a number of additional mammalian and plant species, including those for the laboratory mouse (Gregory *et al*., 2002), laboratory rat (Krzywinski *et al*., 2004), rice (Tao *et al*., 2001), and maize (Cone *et al*., 2002) genomes. These maps have played, and continue to play, important roles in genome sequencing efforts. For more information on the use of physical maps in genome projects, (*see* Article 3, **Hierarchical, ordered mapped large insert clone shotgun sequencing**, Volume 3, Article 24, **The Human Genome Project**, Volume 3, and Article 8, **Genome maps and their use in sequence assembly**, Volume 7). The remainder of this review will discuss more specifically the current strategies used for fingerprint map construction that have evolved from the pioneering work of the past 30 years.

3. Fundamentals of fingerprint map construction

3.1. *Overview of the fingerprinting process*

The bottom-up approach for constructing fingerprint maps, also referred to as a contig-building strategy, can be divided into a fingerprint data generation (wet-lab) component and a contig construction (computational) component. The process is outlined in Figure 1, and encompasses the following basic steps: (1) construction of a large-insert clone library representing many copies of the genome, (2) DNA purification and restriction endonuclease digestion of a number of clones that together represent redundant coverage of the genome, (3) size separation of the restriction fragments by electrophoresis, (4) restriction fragment detection and size determination, (5) comparison of restriction fragment patterns between all clones to determine similarity, (6) assembly of clones with highly similar restriction fragment patterns into groups of ordered, overlapping clones (referred to as "contigs"), and (7) comparison of fingerprint patterns between clones at contig edges to identify moderate but still significant similarities, indicating joins between individual contigs, and thereby constructing larger contiguous regions of the genome. The end

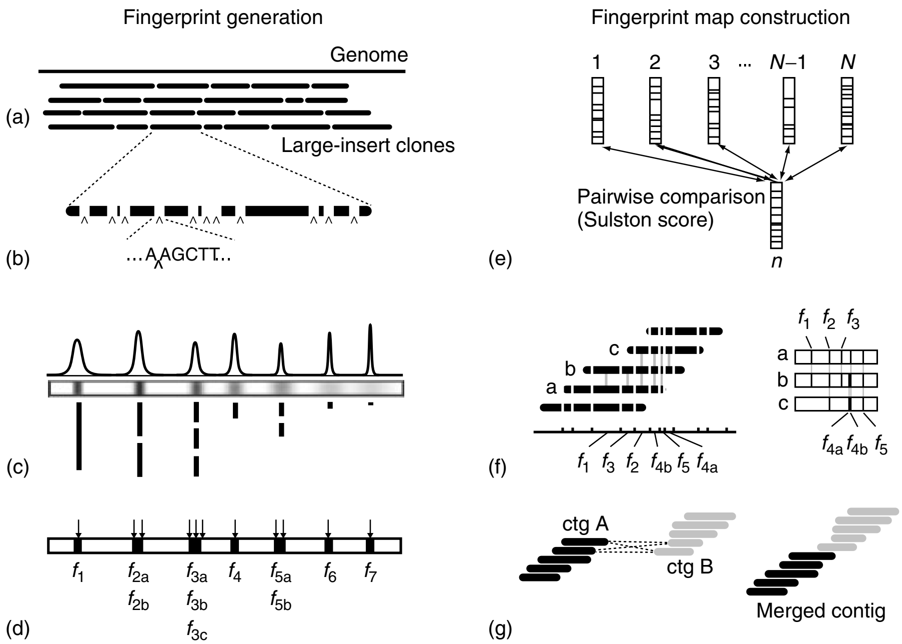

Figure 1 Overview of clone fingerprint data generation and map construction. The two components are shown, fingerprint generation on the left and map construction on the right. Fingerprint generation (a–d): (a) Generation of a large-insert clone library that represents the genome at a high level of redundancy. (b) Clones are sampled randomly from the library and digested with restriction endonuclease, here illustrated with the enzyme *Hin*dIII, with recognition sequence A|AGCTT. (c) Size separation of the restriction fragments by electrophoresis. Stylized data are depicted, with electrophoresis progressing from left to right. Top, chromatogram derived from fluorescently labeled fragments separated on automated sequencer; middle, fragments separated on an agarose gel and visualized with fluorescent DNA dye; bottom, actual restriction fragments. (d) Fragment detection and size determination. Each detected fragment is denoted with f_n where n indicates a particular fragment size. Note that multiple fragments of the same size can be detected on agarose gels. Size determination is made by comparison and interpolation to the fragment pattern of an analytical marker (not shown), composed of DNA fragments of known size. Map construction (e–g): (e) Fingerprint data are stored as an ordered list of fragment sizes and/or mobilities for each clone (depicted here as a size ordered set of fragments). Comparison of fingerprints between all clone pairs is first performed to determine the similarity of fragment patterns. (f) Clones with highly similar fingerprint patterns (depicted on the right) are grouped into ordered sets representing overlapping clones (depicted on the left). Order within the contig is deduced by the progression of ordered fragments across fragment patterns (right, bottom). (g) Map contiguity may be increased by subsequent comparison of fingerprint patterns between clones at contig edges (depicted on the left) to identify moderate but still significant similarities that can join contigs into a single structure (depicted on the right)

result of this process is a physical map represented by sets of ordered, overlapping clones. Depending on the fingerprinting technique used, the map may also reflect the underlying restriction fragment map of the genome. Assembly of the fingerprint data into contigs (steps 5–7, above) is performed with the assistance of a program called Fingerprint Contigs (FPC) (Soderlund *et al*., 1997; Soderlund *et al*., 2000). The details of the computational aspects involved in using clone fingerprint data to assemble contigs is described elsewhere (*see* Article 19, **Restriction fragment fingerprinting software**, Volume 3 and Article 1, **Contig mapping and analysis**, Volume 7) and will not be covered here.

One might expect at the end of this contig-building process that each chromosome will be represented by a single contig; however, in practice, this is not achieved owing to the effect of a number of technical factors that may each contribute to varying degrees, including reduced representation (or lack of representation) in the library of certain genomic regions, lack of genome coverage as a result of the random sampling approach, and unrecognized clone overlap. These are discussed in more detail below.

3.2. Fingerprinting methods

There are two basic clone fingerprinting techniques that have evolved from the early work in *C. elegans* and *S. cerevisiae*, differentiated primarily by the method in which restriction fragments are separated and detected. In one method, restriction fragments are resolved by size on agarose gels and detected by staining with a sensitive DNA dye. In the other method, fragment separation is achieved using polyacrylamide electrophoresis and fragments detected via either radioactive or fluorescent labels.

The agarose gel-based technique (Marra *et al*., 1997; Schein *et al*., 2004) was developed from the method used to construct the *S. cerevisiae* fingerprint map, and was the first method to be widely applied to genome physical map construction. In this method, clone DNA is digested to completion, typically using a single enzyme with a 6-bp recognition site, and the fragments separated by electrophoresis on agarose gels. Analytical marker standards with known fragment sizes are loaded in frequent intervals along the gel to provide a sizing standard. Restriction fragments between approximately 600 and 30 000 bp can be resolved and reliably detected (Fuhrmann *et al*., 2003). Essentially, all restriction fragments generated from each clone (typically on the order of 23 fragments per 100 kb for a single enzyme digest) are detected with this method, providing the potential of deriving an ordered restriction map of each contig. In practice, however, the restriction map is only partially ordered, consisting of a series of fragment "bins", each bin containing one or more fragments. The relative order of the bins is determined, but the order of multiple fragments within a bin is not. The detection of all fragments and their sizes has several advantages: insert sizes can be determined individually for each fingerprinted clone, which can be a useful constraint when including end sequences of the BACs into a genome sequence assembly or when assessing BAC end sequence alignments to a genome sequence assembly; the estimated size of the overlap between any two clones can be calculated directly by summing the size of shared fragments detected, which has practical application when selecting from a contig a tiling set of clones, for example, a minimal tiling set of clones for sequencing or for representation on a genome array (*see* Article 16, **Microarray comparative genome hybridization**, Volume 3); verification of sequence assembly accuracy can be performed by comparison between experimental fingerprint fragments and an electronic digest of the corresponding sequence, which can be particularly useful in detecting collapses in the assembly due to the presence of repetitive sequences.

The polyacrylamide-based fingerprinting techniques currently used were developed from the method used to construct the *C. elegans* fingerprint map. In this

method, fragments are separated by electrophoresis on automated sequencers, either slab-gel based or, more commonly now, capillary based. Only those fragments that fall within a size range of approximately 70–500 bp are detected, and multiplets are not reliably detected. In order to generate a sufficient number of fragments within this size range, the DNA is digested with two or more enzymes. One of the enzymes cuts frequently within the genome and leaves a blunt end. The other enzymes typically have 6-bp recognition sites and leave an overhang. The vast majority of the resulting fragments have one blunt end and one end with an overhang, and detectable fragments represent approximately 15% of the clone DNA. The fragments are labeled at the 6-cutter end with one or more fluorescently labeled dideoxy nucleotides. There are several variations of this approach. In one method, a single 6-cutter enzyme is used, either Type II (Gregory *et al*., 1997) or Type IIs (Ding *et al*., 2001) and a single labeled nucleotide is added. A number of fragments similar to that with the agarose method are detected. In an alternative for the latter approach, the overhang is fully sequenced (Ding *et al*., 2001), linking several bases of sequence information to each detected fragment. In a second method, four different 6-cutter enzymes are used, each labeled with a different fluorescent base (Luo *et al*., 2003), which adds restriction enzyme site information to the fragment size for each detected fragment. This method generates on the order of 78 fragments per 100 kb. One advantage of these methods over the agarose method is increased sizing accuracy, which is typically on the order of 1 bp. The increased number of fragments and added information content of two of these methods also provides the possibility of detecting smaller clone overlaps than with the agarose-based method, which may result in greater map contiguity.

3.3. Factors affecting genome representation in clone libraries

Genomic clone libraries are typically constructed from genomic DNA that has been fragmented by partial restriction endonuclease digestion. The distribution of restriction enzyme recognition sites within a particular genome is therefore an important consideration prior to selection of an enzyme for use in library construction. If there exist regions in a genome where the distance between neighboring recognition sites for a particular enzyme is greater than the maximum fragment size that can be cloned, then these regions will not be represented in a genomic library constructed using that enzyme. If a single restriction endonuclease suitable for partial digestion of the DNA cannot be identified, then construction of two or more libraries, each generated using a different restriction enzyme, can compensate to some extent if the distribution of restriction sites for each enzyme within the genome is complementary (e.g., enzymes with different G/C content in their recognition sequences). Analysis of the fragment size range generated by a complete digestion of the genomic DNA with a candidate enzyme can indicate whether there are regions of the genome that will not be cloned. The size limit of cloneable fragments is of course dependent on the vector selected for library construction. Bacterial artificial chromosome (BAC) vectors (Shizuya *et al*., 1992) are currently the vectors of choice for constructing large-insert genomic libraries for purposes of restriction fingerprint mapping. BAC vectors are capable of cloning segments of foreign DNA of up to 300 kb,

although insert sizes generally range from 100 to 200 kb. The cloned DNA is stably maintained, the rate of chimeric constructs is very low, and the clones are easily manipulated in the laboratory. However, there may be genomic sequences that are not readily cloned or easily propagated within bacterial hosts (e.g., heterochromatic DNA), and this can result in some bias in genome representation in a library.

3.4. Redundant genome sampling in a random-clone approach

In a random-clone fingerprinting strategy, clones from a genomic library are arrayed and sampled at random, with no a priori knowledge of where the clone inserts originated in the genome. Each successive clone that is sampled from a library may represent a completely unique region of the genome or it may overlap in whole or in part with one or more previously sampled clones. The first clones sampled from a library each has a high probability of representing a unique region of the genome, so the rate at which unrepresented regions of the genome is sampled with each additional clone is high. As the number of sampled clones increases, the probability decreases that each additional clone contains previously unsampled, unique DNA, and the rate at which unrepresented regions of the genome are sampled begins to decrease with each additional clone. In order to achieve complete, or nearly complete, representation of the genome in a random-clone approach, it is therefore necessary to sample many more clones (redundant sampling) than would be required to represent the genome if the clones were simply laid end to end.

The level of redundant sampling undertaken for a fingerprint mapping project is a function of the desired level of genome representation, the fraction of shared DNA between clones that is required to detect true clone overlaps (i.e., the sensitivity of overlap detection), and the relative number of contig gaps that is deemed acceptable. Given a truly nonbiased, randomly arrayed clone library, approximately fivefold genome redundancy (5X coverage) is necessary to provide substantially complete representation of a genome (Michiels *et al*., 1987). At fivefold redundancy, on average each nucleotide is represented in five different clones or, put another way, each clone overlaps on average with four other clones. This would roughly equate to 80% shared DNA between adjacent clones in the genome, a relatively substantial overlap. However, this is a calculated average, which means that half of the adjacent clone pairs will overlap by something less than 80%. Thus, for example, if 80% shared DNA is the minimum amount of overlap required to differentiate between true clone overlaps and false-positive overlaps during fingerprint contig assembly, half of the adjacent clone pairs in the genome will fail to satisfy this requirement. This will result in a large number of contig gaps in the assembly due to undetected clone overlaps. To minimize the number of contig gaps, the effective genome coverage in sampled clones must be increased to a depth that ensures that the majority of the genome is represented by adjacent clone pairs that overlap by the required amount.

3.5. Clone overlap detection and contig gaps

For any particular fingerprinting project, the level of redundant clone coverage required is dependent on both the size of the genome and the sensitivity of detection

of clone overlap, the latter of which is based on fingerprint similarity and is a function of clone size and fingerprinting technique. Clone overlap is essentially calculated as the relative proportion of common fragments shared between two clone fingerprints. Since larger genomes require more clones to represent them than do smaller genomes, the probability that there are two unrelated clones sharing by chance a certain number of fragments of the same size is also increased. Thus, as the size of the genome increases, the likelihood of detecting false-positive overlaps given a particular requirement for clone similarity also increases. The required amount of calculated overlap between two clones that is accepted as representing true overlap for purposes of contig construction must therefore be increased for large genomes relative to smaller genomes, and this will affect the level of redundant coverage selected. Mathematical descriptions and analyses of the various effects of these factors have been described (Lander and Waterman, 1988; Branscomb *et al*., 1990). For fingerprint maps of mammalian-sized genomes, a number of clones representing 10–15X genome coverage are typically fingerprinted.

Short Specialist Review

Restriction fragment fingerprinting software

Carol A. Soderlund
University of Arizona, Tucson, AZ, USA

1. Introduction

A physical map provides an ordering of clones, markers, or both. A physical map may be built using marker-clone associations (*see* Article 13, **YAC-STS content mapping**, Volume 3), where the markers are ordered such that they are contiguous for each clone (e.g., Alizadeh *et al*., 1995; Soderlund and Dunham, 1995). Alternatively, a physical map can be built using restriction fragment fingerprinting. In this case, a clone is digested with one or more restriction enzymes and the resulting fragments are measured. Two clones may overlap if they have a sufficient number of similar fragments. Overlapping clones are arranged into contigs to position the clones relative to each other. Whole-genome fingerprinting was first performed in the late 1980s (Coulson *et al*., 1986; Olson *et al*., 1986). Techniques for agarose-based fingerprinting have been greatly improved in order to reduce the amount of error (Marra *et al*., 1997). An alternative fingerprinting method called *HICF* (*High Information Content Fingerprinting*, Ding *et al*., 1999, 2001; Luo *et al*., 2003) has recently emerged. The most popular software for assembling fingerprinted clones into contigs is FPC (FingerPrinted Contigs, Soderlund *et al*., 1997), which works with either agarose or HICF. The FPC V7.2 software, executables, tutorial, and web-based tools are available from **http://www.genome.arizona.edu/software/fpc**.

2. The FPC software

FPC takes as input files of clones, where each clone is represented by a set of restriction fragments (often referred to as *bands*). It compares all pairs of clones, counts the number of shared bands, and computes the Sulston score (Sulston *et al*., 1988), which is the probability that the shared bands are just a coincidence. The user sets a cutoff and all clone pairs that have a Sulston score below the cutoff are considered overlapping. The assembly algorithm clusters clones such that each clone in a contig has a good overlap with at least one other clone in the contig. It then orders the clones by building a consensus band (CB) map, which is an approximation of the way the bands are ordered along the underlying genome. The clones are aligned to the CB map to give them an approximate position.

The measurement of the bands is not exact; so to compensate for this, the user supplies a tolerance to be used by FPC. If two bands are of the same value within plus/minus of the tolerance, they are considered to represent a fragment of the same size. False positive (F+) and false negative (F−) bands can cause F+ and F− clone overlaps; therefore, the accuracy of the band measurement is very important. It also affects the positioning of the clones; the more error in the data, the more imprecise the clone coordinates (Soderlund *et al*., 2000).

The user-supplied cutoff must be set to reduce F+ and F− overlaps. F+ overlaps result in chimeric contigs, which can generally be detected by an abundance of Q (Questionable) clones, where a Q clone is one in which the ordering routine cannot align 50% or more of the bands to the CB map. F− overlaps cause the clones to assemble into many contigs. For example, given a cutoff that results in 70% overlap between clones (which is typical for agarose-based fingerprints), a genome size of 2400 Mb, clones of size 150 000, and a 17x coverage, the clones will assemble into 1574 contigs if the clones are evenly distributed (Lander and Waterman, 1988). Since some regions are not cloneable and the coverage of clones is not evenly distributed, the number of contigs will be much greater than 1574.

The main FPC automatic functions are: (1) Build contigs, (2) IBC (Incremental Build Contigs) adds new clones to existing contigs and merges contigs, (3) DQer reassembles contigs with over a given number of Q clones using a more stringent cutoff, which reduces F+ overlaps, and (4) End Merger compares clones at the end of contigs using a less stringent cutoff and automatically joins contigs (V7.2 only), which reduces F− overlaps. As these functions do not fix all F+ and F− overlaps, FPC also contains many interactive queries and edit functions so that the user can manually fix the remaining problems (Engler and Soderlund, 2002).

2.1. *Using markers and anchors in FPC*

Fingerprints can be assembled to order the clones relative to each other, but do not order contigs or position them on the chromosome. Genetic markers or radiation hybrid markers (*see* Article 14, **The construction and use of radiation hybrid maps in genomic research**, Volume 3) have order and location on the chromosomes. If these markers have been hybridized to fingerprinted clones, the data can be entered into FPC and used to anchor contigs to chromosomes. Unanchored markers, such as many of the ESTs, are often hybridized against the clones. These marker-clone associations can be entered into FPC, which gives the markers an approximate ordering. The presence of markers in the FPC map is also important for verifying fingerprint data and can be used in conjunction with the fingerprints for assembly. The contig display (see Figure 1) provides a versatile way of viewing the clones, markers, and anchors.

When BESs (BAC end sequences) or sequenced clones (draft or finished) are associated with clones in the map, additional sequenced markers can be added electronically. This is done using the FPC function BSS (Blast Some Sequence), which takes a file of markers, compares them against the sequences associated with FPC clones using BLAST (Altschul *et al*., 1997), megaBLAST (Zhang *et al*., 2000), or BLAT (Kent, 2002). The hits can be added to the FPC map as electronic markers.

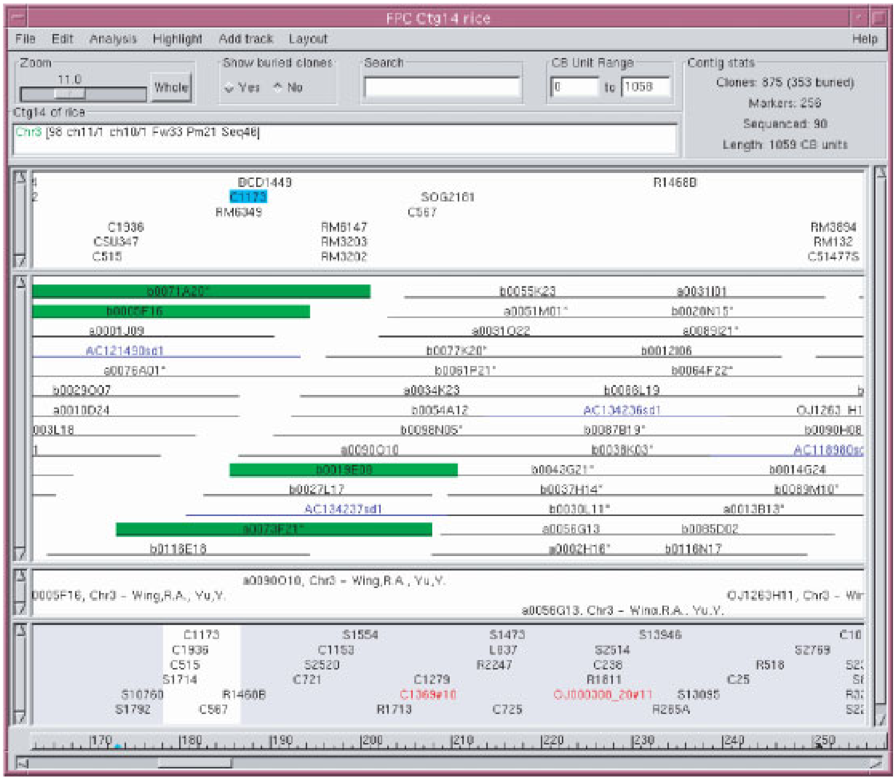

Figure 1 Each of the four regions with a scroll bar on the left is referred to as a *track*. The first track shows the markers. Selecting a marker highlights the clones that it is contained in, as illustrated by marker C1173. The second track shows the clones. The blue clones starting with “A” are sequenced clones from Genbank that have been digested in silico using FSD (FPC Simulated Digest, Engler *et al*., 2003). The third track shows remarks associated with clones or markers. The remarks shown here are attached to the simulated digest clones. The lowest track shows all anchors, which are markers that have a chromosome position. Anchors shown in red disagree with the majority of anchors as to the chromosome assignment. The chromosome assignment is shown above the first track and has been assigned by an FPC function based on majority rules

2.2. *Sequencing*

FPC is used for selecting clones for sequencing (e.g., The International Human Genome Mapping Consortium, 2001). Until recently, this has been performed interactively with FPC tools. A recent release provides a routine that automatically selects an MTP (Minimal Tiling Path, Engler *et al*., 2003), using sequence similarity or fingerprint overlap. When a draft sequence hits two BESs of clones that are near each other in FPC, this dual information provides a reliable overlap known in bases (e.g., Chen *et al*., 2004). For finding overlaps based on fingerprints, the algorithm looks for overlapping clones that are confirmed by two flanking clones and one spanner. An MTP is selected from the overlapping pairs using Dikstra’s shortest path algorithm (Dijkstra, 1959), giving precedence to sequence-based overlaps.

2.3. Agarose versus HICF

A commonly used implementation of agarose-based fingerprinting uses one 6-base enzyme and produces fragments with an average size of 4096 bases, which results in approximately 30–50 bands per clone. Typically, the program Image (Sulston *et al*., 1989) is used to determine the migration rate of the fragments and the corresponding sizes of each band. The accumulative size of fragments is used as the approximate size of the clone. A bottleneck with this method is the human time spent in interactively calling the bands in Image; this problem has recently been resolved with BandLeader (Fuhrmann *et al*., 2003).

HICF uses multiple enzymes and detects the terminal base of each fragment. Hence, two bands are considered the same if they have the same size and terminal base pair. The bands are run on a sequencing machine so that we have high-precision measurements of the bands. The bands sizes range from 50 to 500, and clones typically have over 100 bands; note that the bands only cover a subset of the clone, so they cannot be used to calculate the approximate size of the clone. Though FPC does not take base information as input, Ding *et al*. (1999) developed a simple scheme to encode the base in the fragment size.

Acknowledgments

This work was begun at the Sanger Centre, Hinxton, England. Continued work has been funded by grants USDA-IFAFS #11180 and NSF #0213764. Fred Engler, James Hatfield, William Nelson, Ian Longden, and Steven Ness have made significant contributions to the FPC software and documentation.

Synteny mapping

Simon G. Gregory
Duke University Medical Center, Durham, NC, USA

Comparisons between genomes reveal homologous sequences that reflect their common evolutionary origin and subsequent conservation. Segments of DNA that have function are more likely to retain their sequence than nonfunctional segments, as they are under the constraints of natural selection during evolution. Therefore, DNA segments that are conserved between species are more likely to encode similar function. Sequence comparisons between species provide information on gene structures and may reveal regulatory elements. Experience has shown that such comparisons benefit from the use of sequences from a variety of species representing a range of evolutionary divergence. Sequence conservation between species, within genic and nongenic regions, can be utilized for the construction of physical maps. These clone-based maps can underpin the generation of genome-wide sequence, provide regional coverage for directed sequencing efforts, or provide resources for genomic interrogation, for example, using fluorescence in situ hybridization (FISH), comparative genomic hybridization (CGH), or array CGH.

Similarity between genomes is evident at the level of long-range sequence organization where the order of multiple genes on a single chromosome is conserved, or where the chromosomal location of multiple genes, but not necessarily their precise order, is conserved (Nadeau and Taylor, 1984; DeBry and Seldin, 1996; Nadeau and Sankoff, 1998). In general, the degree of similarity at all levels is higher between species that are more closely related on an evolutionary scale, that is, diverged more recently from a common ancestor. Ultimately, comparison of the finished reference sequence of each organism is required to detect every conserved segment, and from this to deduce all the chromosome rearrangements (translocations, inversions, duplications, deletions, and gene conversion events) that have occurred between species. The ability to align the different genome maps over their entire length simultaneously defines the syntenic relationship between them at a new level of resolution and accelerates the process of sequence generation and other biological studies.

The recent revolution in large-scale genomic analysis has already yielded near-complete DNA sequences of a diverse range of organisms, including bacteria, yeast, worm, fly, dog, mouse, and man (Fleischmann *et al*., 1995; Churcher *et al*., 1997; The yeast genome directory, 1997; The C. elegans Sequencing Consortium, 1998; Adams *et al*., 2000; Lander *et al*., 2001; Venter *et al*., 2001; Waterston *et al*., 2002; Kirkness *et al*., 2003). Assembly of each large genome sequence to

date has been underpinned by production of a comprehensive map of overlapping large-insert bacterial clones (e.g., cosmids; Collins and Hohn, 1978) or bacterial artificial chromosome (BAC) clones (Shizuya *et al*., 1992; Coulson *et al*., 1986; Olson *et al*., 1986; Bentley *et al*., 2001; McPherson *et al*., 2001; Gregory *et al*., 2002) for sequencing, and in some cases also for integration with whole genome shotgun sequence data (Adams *et al*., 2000; Venter *et al*., 2001). Mapped clones provide invaluable information to identify and help eliminate incorrect assemblies between repetitive sequences, to provide substrates for targeted finishing (e.g., to >99.99% accuracy; Green, 2001; Dunham *et al*., 1999; Waterston and Sulston, 1998), and as a resource for experimental studies such as FISH (du Manoir *et al*., 1993) and metaphase and array-based CGH (Kallioniemi *et al*., 1992; Pinkel *et al*., 1998; Ishkanian *et al*., 2004). The study of other large genomes, particularly those with high levels of repetitive sequence (like that of the mouse), requires physical maps of a similar standard as a prerequisite for the production of finished sequence, either on a genome-wide scale or to provide access to any region of interest, which may be located in the map using landmarks such as known genes or genetic markers. Clones that are used for the assembly of these physical maps permit specific regions to be targeted for further investigation and, in particular, for the determination of the complete and accurate DNA sequence separately from other clones within the physical map. Because the source of the genomic sequence is generated clone by clone, problems encountered with sequence assemblies are similarly restricted to

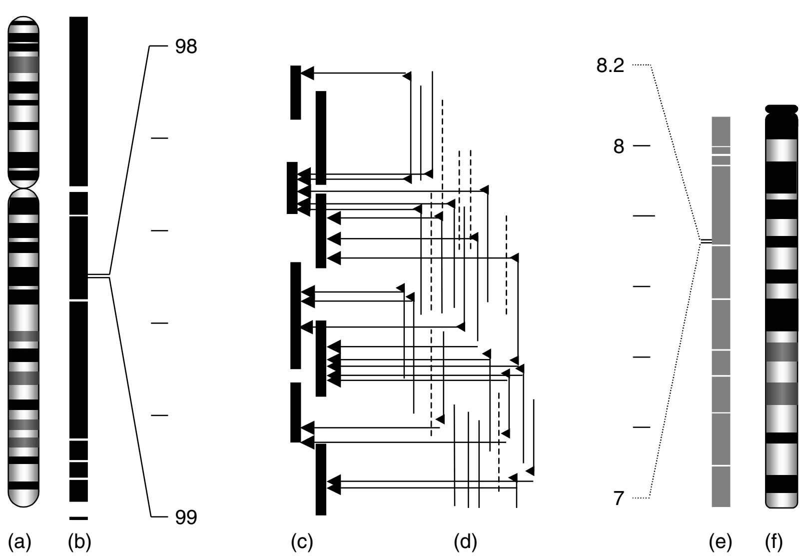

Figure 1 Construction of the physical map of the mouse genome using human genomic sequence as a reference. Finished human sequence from large-insert bacterial clones (c), originating from the physical map (b) of human chromosome 6 (a), provides the template for the alignment of mouse BAC end sequences (d) that had previously been assembled into fingerprint contigs. Contig assembly using the described strategy resulted in rapid assembly of sequence-ready contig coverage (e) of the mouse genome, including mouse chromosome 4 (f)

individual clones, greatly reducing the complexity of resolution of the problem compared to whole genome sequence assemblies.

The similarity in sequence organization between two genomes provides the opportunity for a reference genome, such as the finished sequence of the human genome, to be used as a framework to assemble the physical map of a second genome, such as the mouse (Gregory *et al*., 2002). The phasic construction of such a physical map of a second genome relies upon the existence of a highly redundant restriction digest database (>10-fold redundancy), the availability of BAC end sequences (BESs), and a genome-wide marker set. Initially, restriction fingerprints of the secondary organism are assembled within a database, such as Finger Printed Contigs (FPC) (Soderlund *et al*., 2000). BESs of the clones contained within these assembled contigs are then aligned to the reference genome, prior to inclusion of independently mapped genomic markers for correct positioning within the secondary organism (Figure 1). The juxtaposition of the clone contigs along the reference genome greatly accelerates the physical map construction process and develops a homology map between the two organisms. The proven success of assembling genome-wide physical maps, the cost of constructing a >10-fold genomic BAC library, and the ease with which genome-wide fingerprint databases can be assembled has led to the construction of several genomic fingerprint databases. While genome-wide fingerprint maps will facilitate the large-scale characterization of many varied species, the construction of small region specific sequence-ready maps will continue to be important for detailed interspecies sequence comparisons (Thomas *et al*., 2002).

Short Specialist Review

Hitchhiking mapping

Christian Schlötterer
Veterinärmedizinische Universität Wien, Wien, Austria

1. The principle of hitchhiking mapping

Hitchhiking mapping is one approach toward the identification and characterization of genes with a beneficial effect in a given context (Schlötterer, 2002; Schlötterer, 2003). The underlying principle of hitchhiking mapping is that a beneficial mutation will either be lost or increased in frequency until it becomes fixed in the population. The spread of a beneficial mutation also affects neutral variation linked to the beneficial mutation ("hitchhiking"; Maynard Smith and Haigh, 1974)). As a consequence, the pattern of sequence variation in the affected genomic region differs from neutral expectations. Population genetics has provided a large repertoire of statistical tests for the identification of genomic regions deviating from neutral expectations (Kreitman, 2000; Otto, 2000; *see also* Article 7, **Genetic signatures of natural selection**, Volume 1).

One of the possible consequences of the spread of a beneficial mutation is a reduction in variability. Figure 1 depicts the reduction in variability around a selected site, obtained from an average over 100 independent computer simulations of a selection event at the same site. In this simulation, the target of selection was unambiguously identified as the genomic region with the most pronounced reduction in variability.

2. Different phases of a hitchhiking mapping study

Hitchhiking mapping studies are carried out on a genome-wide scale to identify those parts of the genome that carry a recent beneficial mutation. In the first phase, a large number of loosely linked markers are analyzed. On the basis of this primary screen, a number of loci are identified, which show the most extreme distortion in allele frequency spectrum. Given that a very large number of loci could be tested in such a primary screen, additional testing is required to distinguish false positives from genomic regions subjected to directional selection.

The second phase of hitchhiking mapping focuses on the genomic region flanking one of the candidate regions identified in the primary screen. As linked sites are more strongly correlated after a selective sweep than under a neutral evolution scenario, the pattern of variation at linked genomic regions could be used to verify genomic regions subjected to a recent selective sweep.

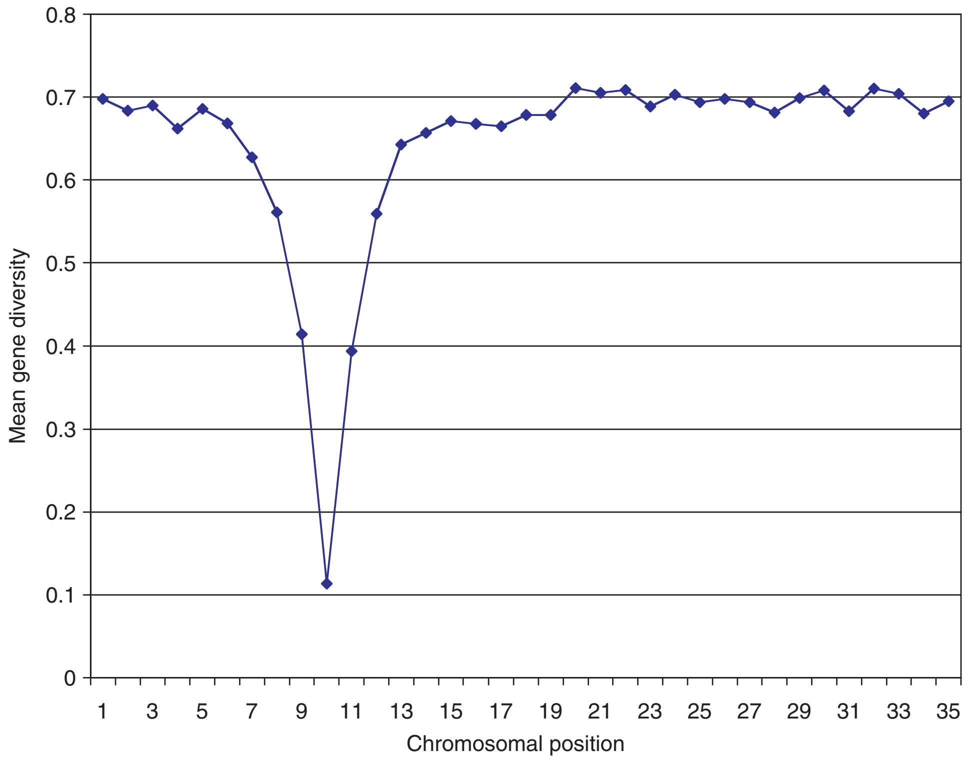

Figure 1 Mean gene diversity determined for 35 evenly spaced microsatellites over 100 simulation runs. For each of the simulations, a selective sweep was assumed to have occurred at the microsatellite No. 10, which shows the most pronounced reduction in variability. Computer simulations were performed with a computer program written by Y. Kim and modified for microsatellites by T. Wiehe. Simulation parameters were: microsatellite spacing = 12 kb, $\tau = 0.001$, $s = 0.001$, $\theta = 5$, $r = 5 \times 10^{-9}$

After the successful verification of a candidate region, the final step of a hitch-hiking mapping study involves a detailed analysis of the genomic region affected by the selective sweep. A comparison of multiple populations with and without a selective sweep could be highly informative for the identification of the molecular changes responsible for the selective sweep.

3. Which marker to use?

The primary screen of many, unlinked markers is greatly facilitated if a highly informative and cost-effective marker is used. Microsatellites are highly polymorphic markers present at a moderate density in most eukaryotic species, making them a good marker choice for first pass genome scans (Schlötterer, 2004). However, SNP (Akey *et al*., 2002) or DNA sequence analysis (Glinka *et al*., 2003) based genome scans have been performed. Microsatellites remain the best choice; the information content of single SNPs is lower than that for a microsatellite locus, and DNA sequencing is more expensive and complicated by the presence of indels.

The second phase requires polymorphism data for several linked genomic regions. Very often, microsatellites are not available at a high enough density. Therefore, DNA sequencing of short (400–800 bp) genomic regions is often the best strategy for the second hitchhiking mapping phase. High-density SNP analysis has also been shown to be informative (Sabeti *et al*., 2002).

The final phase of a hitchhiking mapping project requires a detailed analysis of the polymorphism in the candidate region, which is best achieved by DNA sequencing. Thus, different classes of markers and methods are preferable at the various stages of a hitchhiking mapping study.

4. Potential and limitations of hitchhiking mapping

Recent studies in yeast suggested that even the loss of gene function often does not result in a phenotype that is easily recognized under laboratory conditions (Winzeler *et al*., 1999). Thus, a large fraction of genes cannot be studied by classical genetic approaches. This applies, in particular, to ecologically relevant genes, which, by definition, are highly dependent on the ecological context in which an organism resides. Through the comparison of two groups of individuals adapted to different conditions (e.g., habitat, resistance against diseases, parasites, etc.), hitchhiking mapping provides the opportunity for the identification of genes that recently acquired a mutation, resulting in the phenotypic difference of interest. When the groups are unambiguously defined, hitchhiking mapping offers the advantage that no phenotype needs to be scored in the laboratory. Rather, natural selection has recognized the advantage of the beneficial mutation, which results in the typical molecular signature of a selective sweep. Therefore, hitchhiking mapping can identify even mutations with a subtle or environment-dependent phenotype.

One further advantage of hitchhiking mapping is that no experimental genetic crosses are required. Like linkage disequilibrium mapping, hitchhiking mapping builds upon meiotic recombination events that have occurred in natural populations. As a larger number of meiotic recombination events have occurred in natural populations, hitchhiking mapping could result in a higher mapping precision than quantitative trait locus (QTL) studies requiring experimental crosses.

The signature of a selective sweep is gradually lost as new mutations accumulate (Wiehe, 1998). Hence, hitchhiking mapping is limited to beneficial mutations that occurred in the recent past. Markers with a high mutation rate (such as microsatellites) are better suited for more recent selective sweeps than DNA sequence data. Nevertheless, in Drosophila, hitchhiking mapping was successfully applied to the detection of selective sweeps that occurred about 10 000 years (50 000–100 000 generations) ago. Both microsatellites and DNA sequence analysis detected the signature of the same selective sweep (Harr *et al*., 2002).

Probably the most challenging aspect of hitchhiking mapping is the functional verification of the identified alleles. As the phenotypic effects of these alleles are difficult to study, a comparison of putatively functionally diverged alleles is not straightforward. Nevertheless, at least for some of the identified genes, a sensitized background could be used to test the functional impact of naturally occurring alleles.

Short Specialist Review

The Happy mapping approach

Francis Galibert
Génétique et Développement, Rennes, France

1. Introduction

In 1989, while a Ph.D. student at the University of Oxford, Paul Dear invented a new method for genome mapping, named "Happy mapping", which reflected the use of polymerase on minute amounts of DNA in the procedure. This method is basically an in vitro adaptation of the radiation hybrid (RH) method (Cox *et al*., 1990) in which random subsets of a genome of interest are integrated into the nucleus of a carrier cell to produce a panel of 80 or more independent hybrid cell lines.

This method offers several advantages over the RH method. First, it is possible to apply the Happy mapping method to any genome, including plant genomes, as no cell fusion is involved; second, a Happy panel can be produced in a few weeks as compared to several months for an RH panel; third, a Happy panel contains only the DNA of interest, which makes the analysis of markers easier as there is no possibility of interference with the genomic DNA of the carrier cell. Finally, the final computation of the vectors is simplified, and the resulting map is more robust as a result of the higher and more uniform retention value in each microtiter well of the Happy panel as opposed to the hybrid cell panel.

In the Happy method, minute amounts of genomic DNA, corresponding to less than a haploid equivalent of the genome of interest, are placed in the wells of a microtiter plate (Figure 1). Given the mass of a diploid mammalian genome (~5 pg per nucleus), this corresponds to an average of 2 pg of DNA per well. As a consequence of the limited amount of DNA in each well, only a subfraction of the whole genome is present and, as in the case of radiation hybrid cells, markers located close to each other on the genome tend to be found in the same wells of the microtiter plate. As for RH panels, the ability of a Happy panel to link two markers depends upon the size of the DNA fragments in the wells and, as a rule of thumb, the distance between two markers cannot exceed one-third to one-half of the mean size of the DNA fragments for them to be linked. Owing to the difficulty involved in manipulating very large DNA molecules, the Happy method tends to construct dense maps with at least one marker every megabase. To overcome this limitation, the construction of a Happy panel usually starts by incorporating entire cells or nuclei into agarose beads. The DNA is then gently extracted directly from these beads and subjected to pulsed-field gel electrophoresis. Following migration, bands

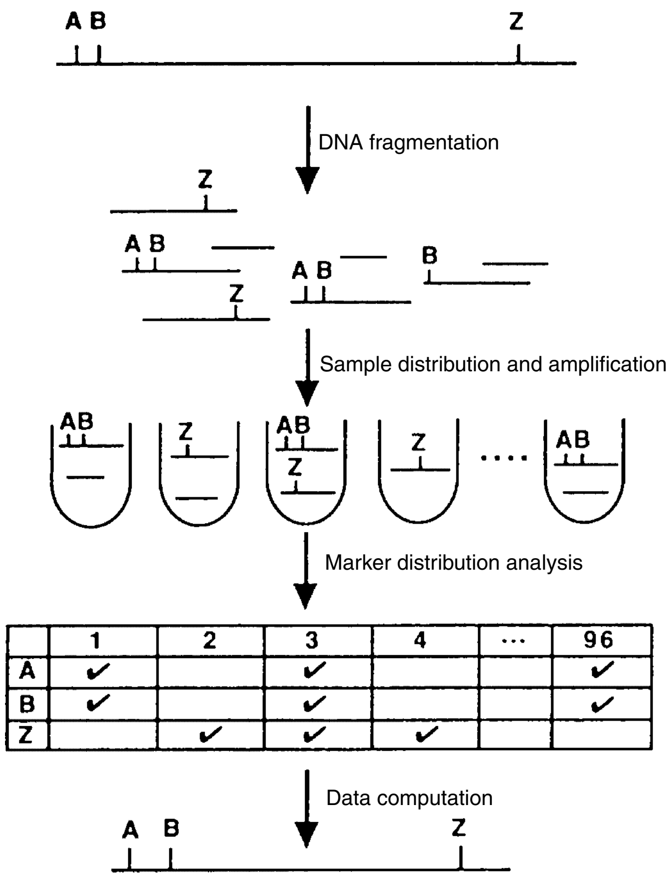

Figure 1 Schematic representation of the Happy mapping method

of the appropriate size – fragments bigger than a few Mb are difficult to obtain – are excised and placed in the wells of a microtiter plate. A series of preliminary experiments are usually necessary to adjust the quantity of DNA placed in each well (between 0.5 and 0.9 haploid genome equivalents). Up to this point, a panel can be readily constructed for any cell type and only requires a bit of practice.

The next stage in map construction is to analyze the distribution of the markers within the panel. This is generally done by PCR as for RH mapping. The immediate advantage of a "Happy panel" as compared to an RH panel is the absence of foreign DNA that could interfere with the DNA of interest during amplification. However, the limited amount of DNA raises a specific problem as the detection of one marker requires two PCR with two pairs of nested primers and a multiplex approach would allow the analysis of a small number of markers only. To overcome this limitation, a whole-genome PCR is required. This poses technical problems that have not yet been satisfactorily resolved. An efficient PCR should satisfy quantitative and qualitative goals. DNA must be amplified 10^7- to 10^8-fold to get enough material for the further mapping of 10^3 or more markers. Even more

importantly, the amplification has to be unbiased, that is, the composition of the DNA after amplification must correspond to its initial composition, such that all the markers present in a well before amplification are present afterward. During the last 10 years, several techniques using different cocktails of oligonucleotide primers and enzymes have been described, but none has met these requirements (Telenius *et al*., 1992; Zhang *et al*., 1992). In these studies, randomness of the product was obtained when a minimum of 30 to 50 DNA molecules was used, but not with just one molecule as in the case of a "Happy panel". Furthermore, the amount of DNA obtained in these studies was limited, prohibiting direct use of the DNA in Happy mapping. Through reamplification of the PCR products, sufficient material could be obtained, but as a sizable fraction (between 30 and 40% depending on the Happy panel) of the markers could not be mapped accurately, PCR-induced representational bias was suspected (De Ponbriand *et al*., 2002).

As a proof of concept of their method, Dear *et al*. (1998) mapped 1001 markers from human chromosome 14. To overcome the PCR bottleneck, they performed inter-Alu PCR with one degenerate primer specific to the repetitive Alu sequence. Although this provided excellent proof of principle, as the resulting map was subsequently shown to match the corresponding human sequence, this sort of map is of little value to gene hunters as these marker sequences are usually nonpolymorphic and not readily usable for synteny comparisons.

It is striking to note that apart from Paul Dear's group and ourselves, no one has ever published a map based on the "Happy technique" despite the potential advantages of this method. Owing to the absence of methods for obtaining sufficient quantities of unbiased amplified haploid DNA, the method has not been used to map any large genomes. Instead, Paul Dear and colleagues have produced genome maps of unicellular eukaryotes of less than 20 Mb (Abrahamsen *et al*., 2004) and of specific chromosomes such as Dictyostelium discoideum chromosome 6 (Konfortov *et al*., 2000). This involved a rather cumbersome two-step amplification approach. The first amplification with a limited yield was done according to Zhang *et al*. (1992) with a random 15-mer primer. In the second amplification step, aliquots of the first amplification product were subjected to multiplex PCR with between 20 and 200 pairs of primers corresponding to the PAC end sequences and additional markers (Piper *et al*., 1998). Finally, using an aliquot of this second amplification, marker-specific PCR was carried out to analyze the distribution of each marker within the Happy panel.

2. Future trends

Efforts to develop a PCR method that results in adequate yields and that can randomly amplify a minute amount of genomic DNA have been moderately successful.

However, the limited DNA yield obtained with the technique described by Zhang *et al*. (1992) has led Paul Dear and collaborators to develop a strategy on the basis of a two-step amplification combined with a multiplex PCR approach to map only a few hundred markers (Piper *et al*., 1998; Konfortov *et al*., 2000). Nevertheless, the potential of the approach and the robustness of the "Happy map" have been well established. Other recent developments, such as those based on DNA microarray

technology or the identification of new enzyme activities, should rekindle interest in the Happy method and lead to the proposal of novel applications.

The development of dedicated microarrays and the possibility of reducing the complexity of large genomes by only amplifying small restriction fragments (Kennedy *et al*., 2003) should lead to new opportunities. It may, for example, be possible to spot PCR fragments corresponding to markers of interest (i.e., corresponding to short restriction fragment produced by a six-nucleotide cutter enzyme) onto functionalized glass and to hybridize them to fluorescently labeled DNA extracted from the different samples of a Happy panel. This approach would detect markers present in each sample instead of asking in which samples each marker is present. If properly developed, it should be possible to use this strategy to derive dense maps of mammalian genomes for which we will shortly have access to sequence information generated by low-pass shotgun sequencing. Other amplification strategies will certainly be developed using the QBeta polymerase sold by several companies and which has been shown to support high yields of random amplification. This enzyme could be used either alone or in combination with the amplification method described by Zhang *et al*. (1992). The attractive possibility of dissecting identified DNA regions or chromosomal bands under a microscope (metaphase spreads) should make it possible to prepare localized markers. It should then be easy to map these limited number of markers on a Happy panel that could be constructed using the currently available method in a few weeks rather than in a few months for an RH panel. These are several possibilities that remain to be investigated now that it has been well established that the Happy mapping method can produce robust maps and could thus be a powerful alternative to the RH method.

Short Specialist Review

Digital karyotyping: a powerful tool for cancer gene discovery

Hai Yan and Darell Bigner
Duke University Medical Center, Durham, NC, US

Human beings are genetically diploid. Normally, there are 23 pairs of chromosomes in the nucleus of a somatic cell, and there are two copies of each gene at its specific genomic locus. However, chromosomal aneuploidy, and gene-specific amplification and deletion are commonly observed in human cancer cells. Although random chromosomal or subchromosomal changes can be attributed to genome instability in cancer cells (Lengauer *et al*., 1997), specific recurring gene copy number variations in cancer cells indicate oncogenes and tumor suppressor genes located within the gained and lost genomic regions, respectively. For example, amplification of Her2/neu in breast cancer (Slamon *et al*., 1989) and deletion of PTEN in glioblastoma (Steck *et al*., 1997; Li *et al*., 1997) have been shown to be the driving forces of tumorigenesis.

In the past decades, the quantitative detection of gene amplification and deletion in cancer genomes has been extensively applied to search for oncogenes and tumor suppressor genes. However, the rate of discovering new cancer genes has been unsatisfactory because of the lack of systematic methods that would enable high-resolution scans of the entire genome. The first accurate whole-genome cytogenetic analyses began in 1956 with a method to visualize and count human chromosomes (Tjio and Levan 1956) by histochemically staining the metaphase chromosomes to resolve 400 to 800 distinct chromosomal bands. Spectral karyotyping (Schrock *et al*., 1996) and multiplex-fluorescence in situ hybridization (Speicher *et al*., 1996) are the modern variations of classic karyotyping, which can reveal both numerical and structural aberrations but are limited in mapping resolution to >10 Mbps. Comparative genomic hybridization (CGH) (Kallioniemi *et al*., 1992) is one of the techniques that has been used successfully for measuring genetic dosage changes in the last decade. Limited by the power of resolution, these methods cannot detect genomic alterations at the single-gene level. Moreover, the large chromosomal regions identified by these methods usually contain a large number of genes. Isolating the gene that has a causal role in neoplasia from the many other genes located in the large altered genomic region constitutes a challenge to cancer researchers. Recently, the completion of the reference human genome sequence has made possible the development of several new techniques for measuring gene dosage at the level of single genes. These methods, including array CGH (Pinkel *et al*., 1998; Cai *et al*., 2002; Pollack *et al*., 1999; Solinas-Toldo, 1997) representational oligonucleotide microarray analysis (Lucito *et al*.,

2003; Sebat *et al*., 2004) single nucleotide polymorphism arrays (Lin *et al*., 2004) end-sequence profiling (ESP) (Volik *et al*. 2003) and digital karyotyping (Parrett and Yan, 2005; Wang *et al*., 2002; Shih Ie and Wang, 2005) as compared with conventional cytogenetics methods, provide an unprecedented mapping resolution that allows a precise localization of the amplified and deleted chromosomal regions.

Digital karyotyping accomplishes gene dosage screening of an entire genome by sequencing of representative, small DNA fragments, called tags, which are contained within the genome (Wang *et al*., 2002). These sequence tags (21 bp each), obtained from specific locations in the genome, contain sufficient information to match a tag sequence to its corresponding site in the genome. The tag density can be statistically analyzed to assess the relative genetic content of different loci. In practice, several detailed steps are needed to isolate the genomic tags. First, depending on the resolution desired, the genomic DNA from a tumor sample is cut by an endonuclease mapping enzyme, such as SacI, with a 6-bp recognition sequence, into representative fragments. The fragmented DNA molecules are then ligated to biotinylated linkers and are further digested with a second endonuclease fragmenting enzyme that recognizes even more frequent 4-bp sequences. DNA fragments containing biotinylated linkers are purified from the remaining fragments. New linkers containing a 6-bp site recognized by MmeI, a type IIS restriction endonuclease, are ligated to the fragmented DNA. The DNA fragments are then cleaved by MmeI, which releases 21-bp tags. Isolated tags are self-ligated to form ditags, PCR-amplified, concatenated, and cloned into bacteria. Every bacterial clone represents a homogeneous plasmid that contains a number of different tags. Practically, approximately 5000 to 7000 clones are sequenced from each tumor sample to establish a digital karyotyping library that collects a total of 160000 to 200000 tags. Tags are computationally extracted from sequence data and uniquely matched to a precise, assembled genomic sequence, allowing observed tags to be sequentially ordered along each chromosome. Tag densities are evaluated over moving windows to detect abnormalities in DNA sequence content in tumor samples. Theoretically, the number of experimentally derived genomic tags within any genomic region that contains the same number of virtual tags should be equal in a normal cell genome. In contrast, a cancer genome, with a significantly genomic copy number change in a given genomic region, then displays an abnormal number of observed tags in that genomic locus.

The major advantages of digital karyotyping over other gene dosage measurement methods are its higher resolution and its unbiased gene dosage readout. The number of virtual tags obtained using the mapping enzyme SacI and the fragmenting enzyme NlaIII is 842,202, based on the July 2003 Human Genome Sequence Assembly, giving a theoretical resolution of approximately 4 kb. Therefore, a resolution at single-gene level can be theoretically achieved if a sufficient number of experimental tags can be collected from a digital karyotyping library. However, the current resolution of digital karyotyping is limited by the number of tags that can be economically sequenced. Therefore, although digital karyotyping shows exquisite sensitivity and specificity for detecting gene dosage changes, practically, the analysis of 100000 filtered tags would be expected to reliably detect gene amplification of $\geq$100 kb, homozygous deletions of $\geq$600 kb, or a single gain or loss of regions

of $\geq$4 Mb in a diploid genome. Nevertheless, the resolution of digital karyotyping is the highest of current high-resolution, whole-genome screens and can provide a heretofore unavailable view of the DNA landscape of a cancer genome. Furthermore, digital karyotyping provides an unbiased gene dosage readout because digital karyotyping directly sequences and counts the tags, which are directly proportional to the amount of genetic material present.

The remarkable power of digital karyotyping for discovering cancer-related genes has been demonstrated by recent studies from several research groups. Wang *et al*. (2004) identified a 100 kb amplified region that contained the gene encoding thymidylate synthase (*TYMS*) in two of four metastatic colon cancers treated with 5-fluorouracil (5-FU). The high specificity of gene identification enabled them to perform further studies to show that the *TYMS* gene is amplified in approximately one-fourth of colon cancers treated with 5-FU, but was not amplified in tumors that had not been subjected to 5-FU therapy. These findings suggested that genetic amplification of *TYMS* is a mechanism of attaining 5-FU resistance. Shih Ie *et al*. (2005) identified a 1.8 Mb amplification region at 11q13.5 in three of seven ovarian carcinomas. Combined genetic and transcriptome analyses showed that *Rsf-1* was the only gene that demonstrated consistent overexpression in all of the tumors harboring the 11q13.5 amplification. Furthermore, these authors found that patients with *Rsf-1* amplification or overexpression had a significantly shorter overall survival than those without the amplification. Di *et al*. (2005), and Boon *et al*. (2005) applied digital karyotyping on medulloblastoma cell lines and discovered gene-specific amplifications containing the *OTX2* gene, a novel medulloblastoma oncogene. The characteristics of *OTX2* gene amplification and this gene's exclusive overexpression in medulloblastoma tumors make it a useful target for molecular-based therapy. Although only a small number of digital karyotyping libraries have been generated in these studies, each study has discovered altered genomic regions that are small enough to identify the critical genes immediately.

Digital karyotyping and other gene dosage screens are important for revealing specific types of genetic alterations in cancer genomes, but not all possible alternations can be detected by these screens. For example, epigenetic alterations such as DNA methylation and histone acetylation, in addition to subtle polymorphism expressional differences, all have the potential to influence tumor progression, yet would go undetected in gene dosage screens. To address these issues, novel genomic approaches, such as named methylation-specific digital karyotyping, have recently been developed (Hu *et al*., 2005). Moreover, genome rearrangements are important in cancer and other diseases, but cannot be detected by digital karyotyping, whereas ESP can complement these techniques by providing structural aberration maps.

Two important practical considerations for applying digital karyotyping technology are sample purity and cost. First, because tumor purity and homogeneity are especially critical for the detection of deletions, adequate pathologic review and sampling of specimens is important for selecting clinical samples. Techniques to obtain highly purified tumor material include affinity-purified cells, short-term tissue cultures, subcutaneous xenograft tumor cultures, and laser-capture microdissection. Second, a typical digital karyotyping library costs approximately

$10000 to $20000 because of large-scale tag sequencing. Therefore, currently, digital karyotyping is not suitable for large-scale, high-throughput screening. Nevertheless, although the technology is expensive, the high-resolution of data obtained from examining only a small collection of tumor cases may justify this expense.

It will now be possible, using various genomic approaches, to provide a bird's-eye view of the genomic landscape of cancer cells. Knowledge of the full spectrum of genetic alterations in the cancer genome at the single-gene level of resolution will enable a systems view of tumor biology and will lead to identification of novel prognostic markers and therapeutic targets.

Introductory Review

The technology tour de force of the Human Genome Project

Elaine R. Mardis
Washington University School of Medicine, St. Louis, MO, USA

In the short span of a few years, genome sequencing centers around the world were required to undergo a transition that effectively doubled or tripled their normal yearly data production, in order to complete the Human Genome Project (HGP) well ahead of its anticipated completion date (Lander *et al*., 2001). Much of what enabled this increased scale of sequence production was a combination of technological discoveries, made in the preceding years, coupled with revolutionary instrumentation developments that occurred in a just-in-time fashion. What fueled our ability to efficiently sequence the genome, even at this hastened pace, was the creation of a high-resolution physical map (McPherson *et al*., 2001). Both the map and the sequence were necessary elements in generating a finished product of high fidelity and completeness, and both were enabled by a technology tour de force.

Early in the HGP, the importance of first generating a physical map of the human genome as an organizing framework for sequencing was recognized, and became the focus of activity for several groups (Olson *et al*., 1989). Overall, the process of physical map generation can be viewed as a stepwise process, whereby the genome is fragmented into relatively large pieces that can be carried by a host cell. These genome fragments are characterized with respect to sequence content (either restriction enzyme recognition sites or other unique sequences) and then fit back together, much like a puzzle, by virtue of shared sequences present in consistent order. As such, the physical map is a low-resolution construct of the genome, and early maps were typically generated for individual human chromosomes, where a single genome center was responsible for one or more chromosome maps. Many of the early chromosome maps were generated by characterizing chromosome-specific fragments in the yeast artificial chromosome (YAC) vector developed by Maynard Olson's group (Burke *et al*., 1987), and these YAC "clones" were characterized by a wide variety of sequence content approaches, as determined by the group generating the map. Just as many of these maps were approaching completion, however, the bacterial artificial chromosome (BAC) vector system (Shizuya *et al*., 1992) was developed to propagate large genomic fragments in a bacterial host, such as *Escherichia coli*. While BAC clones hold smaller pieces of foreign DNA than YACs (100 kb vs. 500 kb, on average, respectively), BACs are much less likely to delete or rearrange the inserted sequence and are more straightforward to harvest from their host cells (*E. coli*). Once scientists had placed fragments

representing a complete human genome into BAC clones (a "library"), the stage was set to revolutionize the physical map generation process by a clever combination of molecular biology methods and computer software. Mainly, this revolution took place by virtue of a scientific and logistic realization that the human genome needed to have a physical map that was generated with a consistent methodology, using a stable clone "currency" (BACs) that could, once characterized and localized, readily provide a genomic segment for DNA sequence determination. The approach, whole-genome physical mapping by restriction enzyme fingerprinting, was initially devised in our Center to provide a BAC-based physical map of the mustard weed genome (*Arabidopsis thaliana*) (Marra *et al*., 1999). The basic approach requires single restriction enzyme digestion of BAC clones whose total length is 10–15 times the genome size, separation of the resulting fragments on high-resolution agarose gels, staining and imaging the banding patterns, and entering the gel images into specialized software. This software then works to iteratively compare banding patterns for one BAC to all other BACs in the database, joining together those BACs that share a percentage of fragments above a preset threshold (Marra *et al*., 1997; Soderlund *et al*., 1997). The result of this process was the generation of "contigs", or collections of related BACs that recreated a specific region of the genome. From these contigs, BACs that represented the minimal amount of overlap between clones ("tile path") were selected for DNA sequencing. Manual review of data also enabled the joining of contigs to bridge gaps in the map. Although not highly automated, the brute force application of this approach (>300 000 BACs were fingerprinted for the human genome) resulted in a map that served as the main reference and coordination point for the sequencing of the genome (Lander *et al*., 2001).

And what of the DNA sequencing efforts required for the HGP's successful completion? How did we manage this massive increase in scale over a relatively short time period? The answer here lies in the cumulative efforts of many molecular biologists and engineers, both in academic and industrial settings, who provided the instrumentation, biochemistry, and technology to enable increased sequence production. Here, several key developments bear mentioning due to their significant impact. First is the development of cycle sequencing, an offshoot of polymerase chain reaction (PCR), which completely changed the face of DNA sequencing in terms of the efficacy with which reactions could be assembled and incubated. Cycle sequencing effectively is single primer PCR, where all components of the sequencing reaction are combined with the template DNA, and incubated with iterative temperature cycles that denature template molecules, anneal primers, and extend the annealed primers in succession, all without need for human interaction (McBride *et al*., 1989; Craxton, 1993). Prior to its introduction, large amounts of template DNA (~1 μg) were needed for each sequencing reaction, because only a single primer annealing and primer extension step could be done (due to the thermal lability of the enzyme). As such, the number of sequencing fragments was equal to the number of extended primers. Prior to loading, these reactions also needed to have the extended primer fragments melted away from the template strands by high-temperature incubation. Cycle sequencing decreased the input template amount by ~5-fold and eliminated several process steps. A second series of key developments centered around the fact that cycle sequencing reactions were

incubated in programmed thermal cycler instruments. These instruments initially accommodated either single or strip tubes, but ultimately (once developed), 96 well reaction plates with a uniform 8 × 12 tube configuration provided a convenient format. The development of 96 (and later 384) well plates with low thermal deformation, coupled with upstream steps that picked clones for sequencing into 96 tube format boxes (Panussis *et al*., 1996), and DNA preparation methods that could be accomplished in a 96 well format (Marziali *et al*., 1999; Mardis, 1994), paved the way to utilize liquid-handling robots that also were programmed to address 96 wells – these initially were "borrowed" clinical chemistry devices doing simple liquid-transfer steps, but ultimately this coupling of 96/384 well format sample containers and corresponding format liquid handling became integrated into more complicated robots that prepared and sequenced DNA in an assembly line fashion (Hawkins *et al*., 1997). A third significant contribution was provided by two related developments in the enzymology and fluorescent labeling of DNA sequence fragments. Sequencing enzymology was impacted by the creation of a mutant thermostable polymerase by Tabor and Richardson (1995), where a single amino acid change in the enzyme enhanced its binding affinity for modified nucleotides such as the dideoxynucleotide "terminators" used in sequencing. This dramatically reduced the time required for thermal cycling, the amount of expensive ddNTPs required per reaction, and improved the peak height disparities in sequence data. A second improvement, from the laboratory of Mathies (Ju *et al*., 1995a,b), utilized the technique of fluorescence resonance energy transfer (FRET) to label sequencing primers, which greatly enhanced the amount of light produced by each molecule and thus further reduced the amount of DNA needed for a sequencing reaction. Later, incorporation of the FRET-based labeling approach onto the ddNTPs (Rosenblum *et al*., 1997; Lee *et al*., 1997) enabled sequencing to transition from a four-tube reaction for each template (one primer and ddNTP mixture for each nucleotide) to a single-tube reaction where the identity of the fragment (A, C, G, or T) was solely coded by the ddNTP (with its corresponding fluorescent group) incorporated at its 3′-end.

Perhaps the most revolutionary progress in high-throughput sequencing during the HGP was that experienced by fluorescent DNA sequencing instrumentation. Initially introduced in mid-1980 (Smith *et al*., 1986a), these instruments used slab gels to separate the DNA sequencing fragments prior to detection and analysis of the resulting data (Smith *et al*., 1986b). Slab gels inherently limited the scale of operations obtainable for several reasons. First, the time, personnel, space, and logistics required to cast large numbers of polyacrylamide gels were limiting. Second, instrument setup with slab gels, including hand transfer of samples from microtiter plate wells into gel wells, was time consuming and error prone. Third, once the samples had run, the resulting gel image required the careful manual placement of tracking lines onto each lane/sample in order to properly extract the underlying sequence data. Again, this was a tedious, error prone and ultimately rate-limiting step, although software programs were developed to hasten the tracking line placement (Cooper *et al*., 1996). The introduction of glass capillary array–based DNA sequencing instruments largely addressed all of these limitations. Namely, the fragment separation matrix was injected into and expelled from the capillaries automatically, obviating the gel casting and associated steps; the samples were

automatically loaded on at the capillary ends by a process called *electrokinetic injection*, eliminating the sample transfer step; and the capillaries were fixed in space relative to the detector, and once localized, data collection occurred at a defined location for each capillary (Mardis, 1999). Steady improvements over time in terms of reducing the time required for separation and detection, enhancing the separation properties of the matrix that enabled longer read lengths, and increasing the stability of the capillaries, matrix, and buffer have enabled throughputs of up to 24 × 96 samples analyzed in a 24-h period, with almost completely unattended operation. This throughput potential stands in stark contrast to the maximum throughput of 3 × 96 samples per 24 h on the most advanced slab gel instrument available prior to the advent of capillary-based sequencers. As such, this final and often rate-limiting step in the process of sequence data acquisition has been successfully addressed, for now.

This brings us to the present day, anticipating what the future of genome sequencing holds and what challenges we will face. As such, the pursuit of sequencing technology is ongoing, which is as it should be. For example, now that we have completed the human sequence, the call for genome sequence from other organisms is steadily increasing, and we are applying the infrastructure, technology, and methods that were put in place for sequencing the human, toward these new pursuits (Stein *et al*., 2003; Waterston *et al*., 2002). Furthermore, now that the human genome sequence is available as a reference point, it makes sense to sequence additional human genomes as a means of coming to grips with the variation that is found when comparing two individuals, and with that found in a diseased state such as cancer (Ley *et al*., 2003).

Introductory Review

The Human Genome Project

Tim Hubbard

Wellcome Trust Sanger Institute, Cambridge, UK

1. Introduction

The Human Genome Project (HGP) has seen many important milestones in its history, but perhaps the most significant was in February 1996 when all the participants (Table 1) agreed that they would do their utmost to ensure that the genome sequence would be freely available to all. They agreed that sequence data would be released without restriction as swiftly as possible and that they would seek no patent protection. By any standards, it was a remarkable agreement. Potentially, large institutions could have patented genes as they went along. Funding agencies agreed with their research leaders that the best way to benefit humankind was to release the sequence swiftly and freely into the public domain. This approach has been vindicated by the massive growth in Internet access to the genome resources (see Section 5), which shows the value the worldwide community places on the sequence.

2. Starting and end points

Three separate proposals were made in the mid-1980s to sequence the human genome (Roberts, 2001). With an estimate of the genome size of 3 billion base pairs (bp) and a cost for sequencing each base of around US$ 10, many researchers fiercely opposed the concept, arguing that financial support would be diverted from other more immediate projects.

The Congress of the United States of America voted in 1988 to support the Human Genome Project, courageously accepting that even if the cost per base sequenced dropped 10-fold, the overall budget would be as much as US$ 3 billion simply for the sequence. The Project was formally announced in October 1990, funded by the US Department of Energy and the Institutes of Health. Around the world, interest in genome projects grew, resulting in the formation of the Human Genome Organization (HUGO), which acted in the early days to discuss priorities and procedures. As the HGP developed, participants joined from the United Kingdom, France, Germany, Japan, and China (Table 1).

From the outset, the HGP had as its goals not only to sequence the human genome but to develop new technologies, to set paradigms using model organisms, to develop mechanisms transfer genome knowledge to the research community, and to consider ethical, legal, and social issues. Most of the scientific goals of

Table 1 Participants in the Human Genome Project

The institutions that form the Human Genome Sequencing Consortium include:	
The Wellcome Trust Sanger Institute,	The Wellcome Trust Genome Campus, Hinxton, Cambridgeshire, UK
Whitehead Institute/MIT Center for Genome Research,	Cambridge, MA, US
Washington University School of Medicine Genome Sequencing Center,	St. Louis, MO, US
Joint Genome Institute, U.S. Department of Energy,	Walnut Creek, CA, US
Baylor College of Medicine Human Genome Sequencing Center,	Department of Molecular and Human Genetics, Houston, TX, US
RIKEN Genomic Sciences Center,	Yokohama-city, Japan
Genoscope and CNRS,	UMR-8030, Evry Cedex, France
Genome Therapeutics Corporation (GTC) Sequencing Center,	Genome Therapeutics Corporation, Waltham, MA, US
Department of Genome Analysis,	Institute of Molecular Biotechnology, Jena, Germany
Beijing Genomics Institute/Human Genome Center,	Institute of Genetics, Chinese Academy of Sciences, Beijing, China
Multimegabase Sequencing Center,	The Institute for Systems Biology, Seattle, WA, US
Stanford Genome Technology Center,	Stanford, CA, US
Stanford Human Genome Center and Department of Genetics,	Stanford University School of Medicine, Stanford, CA, US

the project were significantly exceeded in terms of accuracy or amount of data collected (Table 2).

3. From 230K to 60 000K

In 1990, the longest single DNA sequence was some 230 000 bp, the genome of the cytomegalovirus. Within 10 years, more than 90% of the human genome would be sequenced and the longest contiguous sequence would have grown more than 100-fold, for human chromosomes 21 and 22. Today, the longest contiguous sequence is in excess of 60 000 000 bp.

This production of high-quality contiguous sequence is built upon a phased mapping and sequencing program established by the HGP during its development. The initial aim of the HGP was to produce by 2005 at least 95% of the gene-containing regions of the human genome at an error rate less than 0.01%, producing long runs of DNA sequence (Table 2).

Why should long runs be important? At that time, most of the sequences generated by labs around the world were shorter and of lower quality. But the human genome sequence was unlikely to be reproduced in full in the foreseeable future

and an archival gold standard was considered essential. Much more important, as biologists got to grips with human genes and variation in human genomes, it became apparent that many genes extended over tens or hundreds of thousands of base pairs, making longer sequence runs much more valuable. Similarly, as it was found that variation in the genome occurs at only about one in 1000 bp, accuracy also became an important criterion.

As the HGP progressed, the demand for accurate sequence was balanced against the growing hunger of the research community for more sequence. In many projects, a lower level of sequence quality is sufficient to allow researchers to isolate and analyze the gene(s) they are interested in. To satisfy this hunger, in 1998, the HGP adopted a plan first mooted in 1995 (Waterston and Sulston, 1998) to produce a draft or sketch of the genome as an intermediate product that could be generated rapidly. While not the finished product, the draft would allow much research to be accelerated and would ensure that the majority of the genome sequence was deposited in the public domain swiftly. At the same time, the HGP remained committed to go on and bring the draft sequence up to gold standard quality. The decision to rapidly create a draft was also partly made out of concerns about commercial plans to create a proprietary draft of the genome and the possible undesirable consequences of restrictions on its use (Sulston and Ferry, 2002).

4. Sequencing the genome

Today's high-throughput DNA sequencing is still based on the biochemical reactions and high-resolution methods for DNA analysis developed by Fred Sanger in the late 1970s (Sanger *et al*., 1977). Sanger's lab also pioneered approaches to apply this method to genome-sized sequence fragments and in 1982 published the first whole-genome shotgun (WGS) (Sanger *et al*., 1982) – a method in which a genome sequence is assembled from overlaps between many short sequence "reads" produced by breaking a genome apart at random. However, for very large genomes, it was considered that the very large number of fragments that would be generated by WGS approach would lead to serious assembly problems (*see* Article 25, **Genome assembly**, Volume 3), as would segmental duplications (*see* Article 26, **Segmental duplications and the human genome**, Volume 3). The HGP adopted a more complex hierarchical sequencing approach for this reason and because it facilitated finishing to high accuracy.

In hierarchical sequencing projects, large clones of DNA (called bacterial artificial chromosomes, or BACs) are first produced by "shotgun" fragmentation of the whole genome, each ∼100–200 kb in size. In the early phases of the HGP, a set of landmarks had been established on the 23 pairs of human chromosomes, and many of the BACs could be mapped to the genome using these landmarks. Through the construction of fingerprint contigs of BACs (*see* Article 3, **Hierarchical, ordered mapped large insert clone shotgun sequencing**, Volume 3) 300 000 BACs could be positioned on the genome through the small number of mapped BACs (Figure 1). From these, a minimal set of BACs was chosen that would cover the majority of the human genome (some regions of all large genomes are refractory to conventional cloning methods and are not represented in libraries of BACs). Each

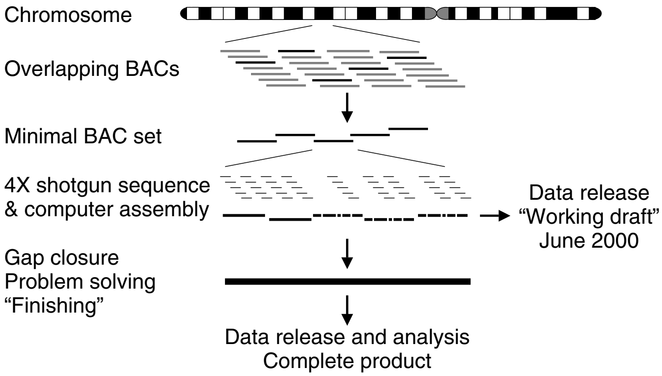

Figure 1 FPC (finger print contigs) are positioned and orientated on human chromosomes via Genethon markers and radiation hybrid (RH) Map. Each FPC is an assembly of BAC clone-based similarities between their restriction digest fingerprints

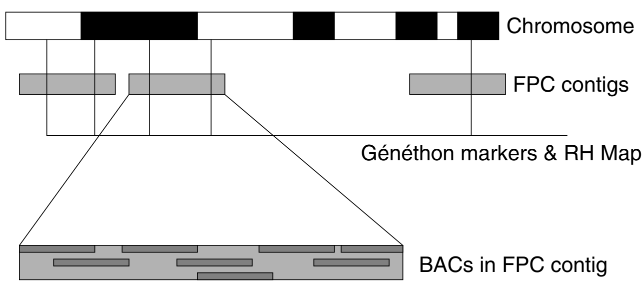

Figure 2 Strategy of HGP was based on selecting a minimal set of overlapping BAC clones to sequence, from libraries covering the genome many times. Each selected clone was then shotgun sequenced to a certain base coverage and then "finished" to close the remaining gaps and resolve problems in a semimanual fashion. A shotgun coverage of 4X means that on average each base in the clone will occur in four different reads

of the minimal set of clones was then subjected to shotgun sequencing (Figure 2). Each was fragmented in turn and subcloned into DNA plasmids that could be used for sequencing. The fragments were typically 2000 bp in length, and about 500 bases of sequence were "read" from each end. First-pass sequencing of 2000–4000 reads per BAC corresponds to reading each base about four times. Assembling these randomly obtained reads generates about 90–95% of the BAC sequence at an accuracy of about 99.9%. This is the draft – the sketch of our genome (International Human Genome Sequencing Consortium, 2001). The majority of the sequencing for the draft was achieved in a little over 12 months, representing an impressive distributed scale up and application of laboratory technology (*see* Article 23, **The technology tour de force of the Human Genome Project**, Volume 3).

Following the announcement of the draft sequence in June 2000, the HGP continued to improve the sequence quality. To fill gaps or to clear up ambiguities, new DNA clones were made using different methods, and sequence was generated

without using clones to fill gaps that appeared to be unclonable. Finishing a genome is a specialist skill and all the participants in the HGP devoted teams to these tasks.

By April 2003, the HGP had surpassed the original goals of the project. The sequence was of much higher quality than the standards set and the amount of the genome represented also exceeded the level of 95% of the gene-containing regions (International Human Genome Sequencing Consortium, 2004). Work continues today to improve the regions that are poorly represented. As the continuity and completeness of each chromosome has been finalized to what appears possible with current technology, each has been analyzed and published. To its credit, the HGP has never claimed to have finished the sequencing of the human genome.

While the human genome sequence has been finished, draft sequences of other vertebrate genomes have been generated using WGS techniques. Recently, the formally private assemblies from the commercial human sequencing project, which championed using WGS techniques for vertebrates (Venter *et al*., 2001), have been released. This has allowed the comparison of a WGS assembly with a clone assembly (International Human Genome Sequencing Consortium, 2004) for the same organism (She *et al*., 2004). The comparison shows that WGS techniques do cause large duplicated regions of genomes to be lost from the assembly with their associated genes (*see* Article 26, **Segmental duplications and the human genome**, Volume 3). It concluded that clone-based approaches are required to resolve such problems. Therefore, while WGS techniques have allowed rapid coverage of new genomes, users must be cautious about overinterpreting differences between genome sequences that may be assembly artifacts.

5. Finding value in our genome

The growth in sequence data in public databases has been exponential since the mid-1980s, requiring continuous development at the database centers to support it. Despite this, the human genome sequencing effort generated an unprecedented amount of sequence in a very short time. It has been a challenge to organize, analyze, and provide access to it, particularly in the face of a huge and growing demand (Figure 3). The HGP has driven the development of two major new public domain Web-based resources Ensembl (Hubbard *et al*., 2002) and UCSC (Kent *et al*., 2002) to organize and provide access to the human genome alongside the existing NCBI resources. The browsers have provided users with web access to an organized representation of the genome sequence, from the time when the genome consisted of around 100 000 fragments at the time of the draft, to the few hundred continuous blocks today. Each allows anyone to download the views, the underlying data, and even the software that makes them work. Each provides links to the experimental data that supports the genome structure and integrates information about sequence variation and disease association. As other vertebrate genomes have been sequenced, they have also provided integrated views of the similarities and differences between them through comparative analysis.

Beyond providing access to the genome sequence, the major focus has been locating the genes in the sequence and annotating their structure. The Ensembl project has been at the forefront, providing consistent gene sets by automatically

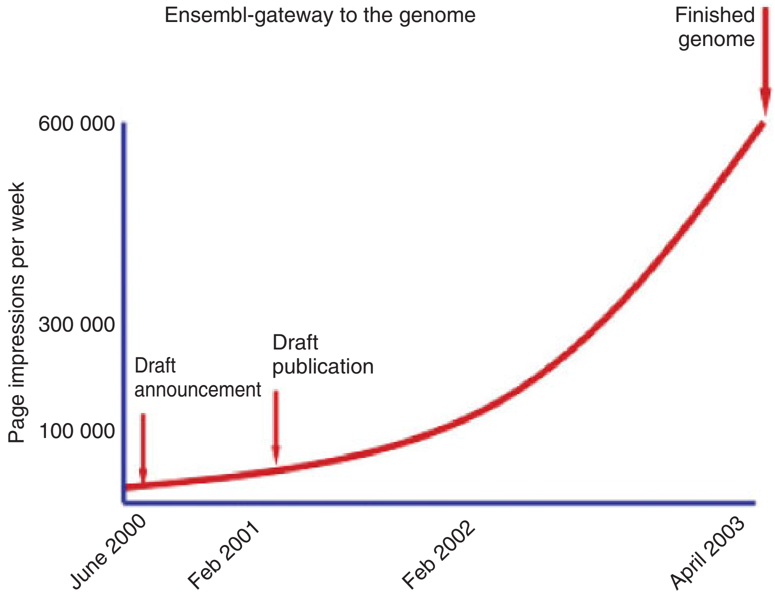

Figure 3 Growth in the use of Ensembl database. Ensembl (**http://www.ensembl.org**) is one of the three major "genome browsers" – Web-based resources that provide assembled information about genomes by creating dynamic web pages from huge supporting databases. The measures shown here are Page Impressions, which is the number of whole pages accessed (and is a more accurate and lower count than "Hits")

annotating the genome on the basis of the alignment of experimental evidence. As the genome has been finished and the collection of high-quality cDNA sequences has increased, a process of curating gene structures has begun to extend and refine this geneset, most notably by the Havana group as shown in their Vega database (Ashurst *et al*., 2005) and by the NCBI RefSeq annotators (Pruitt *et al*., 2003). Recently, Ensembl, NCBI, Havana, and UCSC have begun to collaborate to create the Consensus Coding Sequence (CCDS) resource, which identifies the subset of genes (14 795) for which the annotation of a CDS is agreed across all databases.

Annotation and analysis is very far from complete. Up to now, the focus has been the protein coding genes, and only now are efforts being made to identify and annotate noncoding RNA genes (*see* Article 27, **Noncoding RNAs in mammals**, Volume 3) and microRNAs (*see* Article 34, **Human microRNAs**, Volume 3). Separating functional genes from pseudogenes accurately remains problematic (*see* Article 29, **Pseudogenes**, Volume 3), as does identifying functional alternative transcripts (*see* Article 30, **Alternative splicing: conservation and function**, Volume 3). Ultimately, gene annotation must also extend to promoters (*see* Article 33, **Transcriptional promoters**, Volume 3).

The existence of the sequence and a core annotation has driven researchers worldwide to collect experimental data and perform computational analysis on a genomic scale. One of the most powerful aspects of the genome browsers has been the way that they encourage the integration of external data. Technologies such

as the distributed annotation system (DAS) (Dowell *et al*., 2001), which facilitate this, are based on the recognition that there is too much data that can be related to the genome to be stored in a single database. This virtual integration of annotation will drive progress in our understanding the genome by allowing researchers to easily share and compare different data.

6. Epilogue

The HGP established a clear set of goals (Table 2), within which targets were set and regularly updated in a series of five-year plans. Given the knowledge and capacity for sequencing and analysis at the outset of the Project, these were enormously challenging. Each was met and exceeded. With the goals of the HGP achieved, the centers involved in the project continue to improve the sequence of the human genome, to sequence genomes of other organisms and, above all, to grapple with the real quest of turning this information into biomedical benefit.

Beyond the genome itself, the boldness of the HGP project – to rapidly generate such a critical and huge dataset, through a coordinated public project with immediate public release – has not only transformed biology, but has had a major impact on what is viewed as possible through public research. The HGP has been a triumph for an open data access model of scientific research and has led to policy changes to support this better in future (Dennis, 2003; Editor, 2003). Coming at a time of the success of other open models in software development (open source) and in open access publishing, there are serious questions as to whether this can go as far as open source drug development (Economist, 2004).

Knowledge of our genome sequence means that biologists can do experiments that were not possible in 1999, and can study in detail diseases that had too complex a genetic basis before the catalog of genes was available. Only rarely do biological experiments transform our world. With its careful attention to quality, to free release, and to ethical issues, the HGP has produced a resource that can truly benefit all of humankind.

Genome assembly

Michael C. Wendl, John W. Wallis, Shiaw-Pyng Yang, Asif T. Chinwalla and LaDeana W. Hillier
Washington University, St. Louis, MO, USA

1. Introduction

Historians will undoubtedly rank the Human Genome Project (HGP) among the great achievements of humanity. HGP (*see* Article 24, **The Human Genome Project**, Volume 3) represented an advancement of more than an order of magnitude in size over preliminary "model organism" projects for *Caenorhabditis elegans* (C. elegans Sequencing Consortium, 1998) and *Drosophila melanogaster* (Adams *et al*., 2000), which themselves were breakthroughs. A notable aspect of HGP was the problem of assembling data to deduce the original sequence. In this article, we briefly outline the concept of assembly and the complications arising from various factors, especially sequence repeats. We then describe the two different approaches applied by investigators to generate and assemble human genome data. Finally, we outline the still-evolving assessment of these two projects and attempt to place them in a historic context.

2. The concepts of shotgun sequencing and assembly

In any project, the length of DNA that can be resolved by a single sequencing reaction is invariably a small fraction of the source DNA whose sequence is desired. At their most fundamental level, projects must therefore take the so-called shotgun approach (Sanger *et al*., 1980; Anderson, 1981; Deininger, 1983), whereby small random fragments are read and then reassembled to deduce the original sequence. The assembly process is enabled by oversampling the genome, so that many overlapping substrings of DNA sequence are available for reconstruction.

In a purely random sequence, the assembly problem would be relatively straightforward. The population of repeated sequence strings of a given size decreases in a power-law fashion. In other words, given a specific DNA fragment of length L, a genome would need to be about 4^L bases in size before we would expect to find another copy of this sequence. Disregarding sequencing errors for the moment, suppose we find two human reads that share a specific 30-bp sequence. In random sequence, such a segment would only be expected about every $4^{30} \approx 1.2 \times 10^{18}$ bases. Because the likelihood of finding two copies in the comparatively

paltry 3×10^9 human genome would then be exceedingly small, we would be quite confident in assembling our two reads into a sequence contig. Continuation of this process would result in a gradual conglomeration of reads into ever-larger contiguous regions. In the limit, the complete sequence would eventually be recovered.

Unfortunately, actual DNA contains significant biases, including repeat structures that occur in many largely identical copies. Many instances are much longer than the length of a single sequence read, for example, LINE elements and segmental duplications (Samonte and Eichler, 2002). Sequence data derived from such regions may not be able to be uniquely, and thus, correctly placed in contigs. Consequently, there will be many admissible assemblies, only one of which is correct (Myers, 1999). This phenomenon was especially problematic in the HGP because the human genome contains a large and diverse population of repeat structures.

There was considerable debate as to the most desirable technique for sequencing the human genome (Weber and Myers, 1997; Green, 1997), much of which related to the issue of assembly. The publicly funded project favored what has come to be called the *clone-by-clone approach* (Figure 1a). This method had been used successfully for the preliminary *C. elegans* project (C. elegans Sequencing Consortium, 1998). Here, a minimal set of large-insert clones, for example, Bacterial Artificial Chromosome (BAC) clones, are sequenced individually and assembled in conjunction with the aid of longer-range data, for example, fingerprint maps and clone end sequences. Investigators were optimistic because the clones and the scale of mapping data are typically larger than the scale of repeats. The latter are then essentially encapsulated, permitting a theoretically unambiguous assembly.

Conversely, a newly founded private venture called *Celera* favored a whole genome shotgun (WGS) methodology (Myers, 1999). Here, genomic DNA is

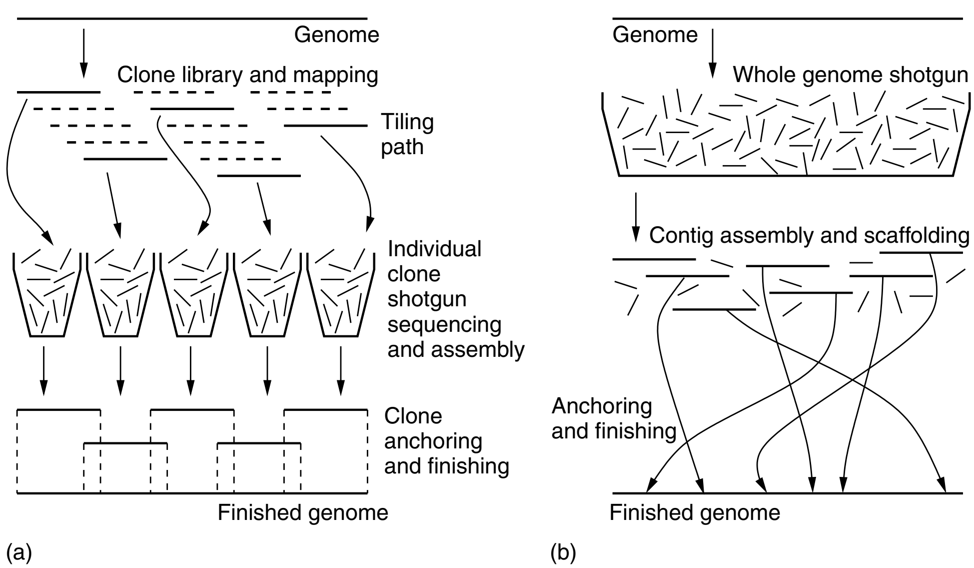

Figure 1 Diagrammatic representation of clone-by-clone sequencing (a) and whole genome shotgun sequencing (b)

sheared and sequenced directly (Figure 1b). Although the WGS technique had already been proven on a number of microbial genomes (e.g., Fleischmann *et al*., 1995), it was unclear whether success in assembling these low-repeat data would extend to the repeat-laden human genome. Proponents based their assessment of feasibility on a number of analyses. In particular, they predicted, based on the Lander and Waterman (1988) theory, that the number of gaps in the sequence would be small (Marshall and Pennisi, 1998). Simulations also suggested that the assembly problem would be tractable, despite the problem of repeats (Weber and Myers, 1997).

Ultimately, these two projects would proceed concurrently, but amid some controversy. WGS advocates maintained that the mapping phase of clone-by-clone sequencing was a slow, expensive, and unnecessary step. Conversely, sentiment in the public project was that a pure WGS assembly would not be well positioned for the downstream phase of completing the genome. In the following sections, we describe each of these two methods in greater detail. We will then draw a few comparisons between the results.

3. Whole genome shotgun approach

A purely WGS method does not utilize long-range mapping data or other nonsequence information to generate an assembly. From an algorithmic standpoint, the main design issue becomes correctly detecting and resolving repeated sequence in the native DNA. In their original proposal, Weber and Myers (1997) cited the so-called double-barrel shotgun approach as a mechanism of overcoming repeat difficulties. Here, inserts are size-selected such that their average length is greater than twice the average read length. These inserts can be sequenced from both ends, which yields not only coverage of the target, but also "mating" information for the pair of reads. That is, the separation distance between these reads is known, at least approximately, from the original insert size. As reads start coalescing into contiguous segments, this mate-pair information is useful in linking sequence contigs into larger "scaffolds". Moreover, it facilitates the encapsulation of repeat structures, as outlined above. This implies the necessity of obtaining mate-pair data over a variety of length scales.

One of the acknowledged liabilities of the WGS method is its susceptibility to errors that arise from corrupted mate-pairing information. Chimerism in clones is always a factor, although this can largely be eliminated by carefully designing and executing protocols. The larger contribution in early WGS projects came from sample tracking errors in the physical handling of DNA and lane tracking errors in analyzing gel images. Overall, such errors meant as many as 10% of the mate pairs were incorrect (Myers, 1999). By the time the pilot WGS project for Drosophila was under way, these mispairings could be reduced to substantially less than 1% (Myers *et al*., 2000). Consequently, mate-pair information could actively be utilized in the assembly process. On this basis, Myers *et al*. (2000) developed the assembly software, ultimately used for both the Drosophila and human genomes, which came to be called the *Celera assembler*.

3.1. Basic assembly methodology

The assembly process nominally begins with a computation that identifies all fragment overlaps. Input is in the form of a set of N fragments that have passed screens for vector and other contamination and that have been appropriately trimmed for base quality. Each new candidate fragment is compared to all existing fragments in the assembly, so that there are a total of $C_{N,2} = N\ (N - 1)/2$ comparisons. Matches of at least 40 bp and 94% similarity were viewed as significant. Such cases represent either a true fragment overlap or a repeat artifact (Figure 2). Misinterpreting the latter case as an overlap would effectively exclude an intervening segment of the original sequence.

In the next phase, sequence "unitigs" are constructed. Unitigs are defined by Myers *et al*. (2000) as local sequence assemblies whose overlaps are not disputed by any other data. However, this does not preclude the possibility of an erroneously assembled repeat region. Unitigs that exhibit uncharacteristically deep coverage are liable to be overcollapsed repeats. A probabilistic measure called the *A-statistic*, α, was devised to detect such cases (see Section 3.2). Large α values are associated with a small likelihood of a repeat-induced assembly error. Some of the more tractable repeat structures can be resolved at this point, using a dynamic programming algorithm to deduce repeat boundaries.

All unitigs determined to be free of repeat encumbrance are passed on to the "scaffolding" phase. Here, unitigs associated by mate-pair information are linked into scaffolds. In addition to yielding the order of unitigs, mate-pair data also allow them to be oriented relative to one another. A single mate pair is generally insufficient to declare a link, however, two or more imply a link to a statistically vanishing chance of error (Myers *et al*., 2000). Longer-range scaffolding is also performed on the basis of BAC end data. At the conclusion of this step, one largely has an ordered, scaffolded assembly of the nonrepetitive portion of the genome.

At this point, a series of increasingly aggressive steps of repeat resolution are undertaken. The first round attempts to place unitigs having relatively small α values and at least two links to other contigs. The next step concentrates on unitigs

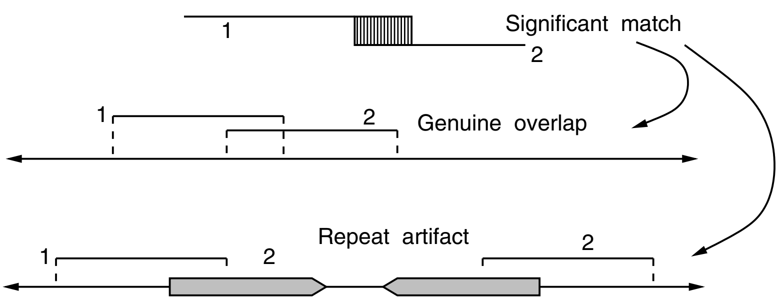

Figure 2 A significant match between two fragments represents a genuine overlap, or the collapse of a region due to a repeat structure. In the former case, fragments 1 and 2 actually derive from the same location in the source DNA molecule, while in the latter case they do not. If a repeat artifact were to be erroneously accepted as a valid overlap, the intervening region would be lost

with only a single link, except that it also requires the placement to be within the context of a tiling of other unitigs. In the original assembler used for the Drosophila project, gaps would be filled with the best overlap tiling of remaining unitigs; however, this step was omitted from the human assembler. At the conclusion of these steps, a consensus sequence is generated.

3.2. *Probabilistic repeat detection*

The primary metric used to detect collapsed repeat regions is the so-called A-statistic, denoted here by the symbol α. This statistic is derived according to a Poisson model for the number of reads one expects to find within a contig of length λ (Figure 3). Specifically, in a genome of estimated length G, the chance of a single read landing within the boundary of the given unitig is λ/G. This approximation neglects end effects, which is justified for large genomes. Presuming the N reads in the project to be independently and identically distributed (IID), one would then expect to find $\mu = N\lambda/G$ reads in the average unitig of length λ. In other words, in the absence of repeats, there would be an average of about μ reads from all contigs of length λ. Because N and λ/G are large and small, respectively, the population of reads essentially follows a Poisson process. That is, the probability of finding exactly k reads in a specific unitig of length λ is the Poisson probability

$$P(k, \mu) = \frac{\mu^k}{k!} \, e^{-\mu} \qquad (1)$$

where $e \approx 2.71828$ is Euler's number.

Now consider a unitig that is actually composed of two regions that have collapsed in the assembly because of a repeat structure (Figure 2). The average such contig would contain 2μ reads, so that the associated probability distribution is $P\ (k,\ 2\mu)$. The A-statistic is simply the base-10 log of the ratio of these two expressions.

$$\alpha = \log_{10}\left[\frac{P(k, \mu)}{P(k, 2\mu)}\right] = \cdots = \mu \log_{10}\ e - k \log_{10} 2 \qquad (2)$$

This expression relates the size of a contig to the number of reads it contains. Small values imply that a contig of given size contains more reads than what could reasonably be explained by random chance. One would then infer a collapsed

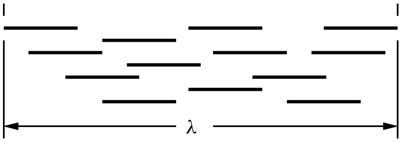

Figure 3 The A-statistic is based on the reads comprising a unitig of length λ bases

repeat. Extensive simulations indicated that $\alpha > 10$ almost always indicates the absence of repeat-related assembly error (Myers *et al*., 2000).

3.3. The human WGS assemblies

Venter *et al*. (2001) described two human shotgun assemblies: the whole genome assembly (WGA) and the compartmentalized shotgun assembly (CSA). Both of these assemblies combined native data generated by the WGS procedure, with additional data obtained from the public sequencing project (*see* Article 24, **The Human Genome Project**, Volume 3). WGS data comprised about 27 million reads derived from 2-, 10-, and 50-kb inserts. Variation in insert sizes provided linking information over several length scales. Public data were added in the form of 16 million synthesized reads, whose nature remains somewhat controversial (see Section 5). An additional 100 000 BAC end sequences were appropriated for long-range linking information.

The WGA assembly was performed essentially according to the algorithm described above. Parameters were selected such that error likelihood for each sequence overlap was about 10^{-17}. Unitigs were evaluated using equation 2, with the resulting set covering about 74% of the genome. After scaffolding and repeat resolution, BAC data were used to close additional gaps. The resulting assembly consisted of scaffolds spanning about 2.85 Gb with sequence coverage of about 2.59 Gb. There were about 11.3 million "chaff" reads that could not be incorporated into the assembly. Average scaffold and contig sizes were 1.5 Mb and 24 kb, respectively, and the total number of contigs was 221 000.

The CSA assembly is based on the premise of isolating smaller regions of the genome according to BAC contigs from the public project, creating localized assemblies using a combination of WGS and public data, and then tiling these assemblies into a larger result (Huson *et al*., 2001). A WGA assembly is then created from each resulting component. Here, about 6.2 million reads were ultimately "chaff". Average scaffold and contig sizes were 1.4 Mb and 23.2 kb, respectively, and the total number of contigs was 170 000. Anchoring of scaffolds to chromosomes was undertaken with the aid of physical mapping information from the public sequencing project (McPherson *et al*., 2001).

4. Clone-by-clone approach

The public sequencing effort explicitly set out with the goal of deciphering the genome in base-perfect form. That is, the error rate should be a maximum of one base in every 10 000. The approach would ideally be one of "divide and conquer" in two sequential steps. On a global level, the genome would be broken into a set of large-insert clones, predominantly BACs (Shizuya *et al*., 1992). At an average length exceeding 100 kb, they are larger than, and thus isolate most repeat structures. In the original plan, a physical map describing the order of these clones would then be generated via the high-throughput fingerprint technique (Marra *et al*., 1997). Here, clones are digested to create "fingerprints" of fragment lengths

(*see* Article 18, **Fingerprint mapping**, Volume 3). These lengths are inferred from band positions on electrophoretic gel images. A significant number of fragment length matches between two fingerprints indicate a likely overlap between their associated clones. The map would enable the selection of a minimally overlapping set of clones, each of which would then be locally shotgun sequenced and finished. With the given complement of information, generating the genome-wide consensus sequence would then essentially be a formality.

Investigators in the public effort deemed this approach more suitable than pure WGS on several grounds. First, WGS had not been proven on a repeat-rich genome and there was concern regarding the ability to use a draft assembly as a substrate for obtaining the base-perfect sequence. The outbred nature of the source DNA posed similar concerns. Moreover, previous projects had demonstrated that the mapping phase was a comparatively inexpensive component, usually less than 10% of total cost (Green, 1997). Improved mapping techniques had also been developed to increase throughput (Marra *et al*., 1997). The intermediate resolution afforded by BAC clones would also allow better targeting of underrepresented regions caused by inevitable cloning biases. Lastly, it would be more compatible with the distributed and international nature of the project.

A pilot phase proved the general feasibility of this approach by finishing a small portion of the genome (Lander *et al*., 2001). Around the same time, an alternative proposal was made to first generate a genome-wide draft sequence, while deferring the finishing phase to a later date. This was driven by two considerations. First, the research community was eager to obtain sequence data as quickly as possible. Second, the commercially funded Celera project sparked strong concerns about the privatization of the human genome and the rise of proprietary human databases (Pennisi, 1999). The public project thus proceeded along a modified version of the clone-by-clone approach as described below.

4.1. Clone selection

The modified project schedule actually necessitated constructing the physical map in parallel with the clone-sequencing phase rather than beforehand (McPherson *et al*., 2001). Consequently, clones could not be solely selected with guidance from a completed map to achieve a minimum tiling path. They were initially selected on the basis of having no overlap with already-sequenced clones or those in the sequencing pipeline. These "seed" clones formed a nonoverlapping set and thus functioned as nucleation sites for sequencing distinct regions of the genome. The fidelity of candidate seed clones was checked by comparing fingerprint bands to neighboring clones, to the clone size, and to its corresponding map fingerprint. Clones from contig ends were explicitly excluded because of their limited ability to confirm bands.

A clone registry was created for managing clones claimed by various participants for sequencing. Seed clones were then extended by picking mating clones having relatively high overlap scores (Sulston *et al*., 1988). Band confirmation and BAC end data were also used in this capacity. In cases where a seed clone sequence was available, overlaps could be further confirmed by comparison to the end sequence

of the candidate extension clone. The average overlap in the final clone set was found to be 47.5 kb (about 28%).

4.2. *Processing individual clones*

Individual large-insert clones were sequenced according to the standard shotgun methodology. Clones were typically sonicated and the resulting fragments were size-selected and subcloned into M13 or plasmid vectors. Details varied among the participants, for example, the proportions in which dye-primer and dye-terminator reactions were used and the type of sequencing platforms that were employed. Shotgun coverage was typically obtained to at least sixfold depth. Reads were assembled predominantly by the Phrap software package (Gordon *et al*., 1998), which uses an overlap-layout-consensus algorithm.

As with the WGS procedure, repeats tend to cause collapsed regions of misassembled reads. However, the localized nature of the assembly decreases the repeat problem substantially. Sequencing errors further complicate the process, which Phrap addresses through base-quality values assigned at the upstream base-calling step (Ewing *et al*., 1998). Phrap does not exploit mate-pair information in the way the Celera assembler does. Moreover, reads are predominantly derived from the same clone source, reducing problems associated with sequence polymorphism.

The first step of the Phrap assembly process determines which reads overlap by evaluating all pairwise subclone comparisons. Anomalies, such as unremoved vector and chimeric reads, are identified as well. Revised quality scores are then computed for each base. These reflect both the raw base-quality scores from the individual reads and any enhancements based on mutual overlap confirmation. The second step determines the optimal placement of overlapping reads to form a layout of the assembly. Here, sequence alignment scores are used in decreasing order to merge contigs. Some joints are rearranged at this stage as well. Finally, consensus sequence is generated for each base position from the columnized layout.

4.3. *Creating a draft assembly*

Assembly at the genome level involves combining the information from the clone overlap physical maps and validating those overlaps using the sequence. Given the draft nature of most of the clones and the fact that some were not yet represented in the map, this phase would not be trivial. After a uniform filtering procedure for contaminated sequences, the assembly approach proceeded in two steps: layout and merging.

The layout step sought to associate sequenced clones with clones on the physical map. Ideally, this would simply be a matter of mapping the names between the two clone sets. However, to minimize mistakes at this stage, two additional quality control procedures were instituted. Fingerprint accuracy was such that *in silico* digests could be used to confirm associations for sequence clones that had few enough contigs. BAC end sequences were also used in a similar capacity. A total of 25 403 clones were linked in this fashion. Fingerprint clone contigs were localized

to their respective chromosomal locations using fluorescence *in situ* hybridization (FISH) data (*see* Article 22, **FISH**, Volume 1) and a variety of radiation hybrid and genetic maps (Lander *et al*., 2001).

Software was then used in the merge phase to order and orient the entire collection of sequenced clones (Kent and Haussler, 2001). Sequence clones were initially aligned to those within the same fingerprint clone contig. Groups of overlapping clones were then built up into larger ordered "barges". Order and orientation were further pursued with the aid of additional information, for example, mRNAs, STSs, BAC end reads, and any other available linking information. A sequence path was then generated from the resulting structure.

The two-phase process used for the public sequencing effort resulted in the draft assembly described by Lander *et al*. (2001). They reported an overall N_{50} length for sequenced clone contigs of 826 kb. This is the length of the contig in which the average nucleotide resides. The N_{50} statistic varied by chromosome. In particular, it was a few orders of magnitude higher for chromosomes 21 and 22, which had already been completed (Dunham *et al*., 1999; Hattori *et al*., 2000). The overall assembly consisted of 4884 sequenced clone contigs and suggested a euchromatic genome size of 2.9 Gb.

5. Epilogue

The public and private genome assemblies were published simultaneously in February of 2001 (Lander *et al*., 2001; Venter *et al*., 2001). Celera's results quickly came under scrutiny based partially upon the amount of public sequencing data that had been appropriated, but more so on the manner in which it had been used. Waterston *et al*. (2002a) described the apparently nonrandom fashion in which synthetic "reads" were manufactured from the public genome assembly and tiled over Celera's own data. They further clarified the extent to which public marker and map data were used by Celera and the nature of the CSA assembly, which was the basis of all the biological analysis reported by Venter *et al*. (2001). Emphasizing the fact that Celera did not report an assembly comprised solely of their own shotgun data, Waterston *et al*. concluded that the published Celera assemblies did not represent a legitimate proof of concept of the WGS method applied to a complex genome. This view was echoed by other members of the scientific community (Green, 2002). Myers *et al*. (2002) rebutted this position, asserting that no linking information was retained in the synthetic reads and that the WGA and CSA assemblies were, in fact, pure WGS assemblies. Vigorous debate continues (Waterston *et al*., 2003; Adams *et al*., 2003; Istrail *et al*., 2004).

It will likely be some time yet before history conclusively places these efforts into a more objective relational context. Celera would certainly have averted any claims by simply eschewing public data. Their initial projections regarding the difficulty of such an assembly based on shotgun data alone, for example, number of gaps and amount of chaff, were clearly incorrect. This created an unexpected urgency for more data. While their use of public data was unquestionably legitimate, it has significantly blurred the comparison between these two fundamentally different approaches.

Regardless, the Celera assemblies might ultimately be relegated to scientific footnotes in the sense that they are unlikely to be extended into finished human sequences. The drive toward completing the genome is proceeding solely on the basis of the public data, and chromosomes are now being individually finished in fairly rapid succession (Deloukas *et al*., 2001; Heilig *et al*., 2003; Hillier *et al*., 2003; Mungall *et al*., 2003; Dunham *et al*., 2004; Grimwood *et al*., 2004). It is somewhat ironic that neither the WGS nor the clone-by-clone strategies appear likely to carry forward in pure form for future projects. Investigators currently favor hybrid approaches that combine aspects of both these techniques (Waterston *et al*., 2002b). The art of sequencing and assembling genomes is clearly an evolving one.

Specialist Review

Segmental duplications and the human genome

Rhea U. Vallente
Washington State University, School of Molecular Biosciences, Pullman, WA, USA

Evan E. Eichler
University of Washington School of Medicine, Seattle, WA, USA

1. Introduction

The process of gene and genome duplication has played a major role in evolution and has sparked the interest of scientists for decades. Susumu Ohno's concept, through his highly influential book "*Evolution by gene duplication*" (Ohno, 1970), focused on the collective effect of duplications, mutations, and natural selection, wherein an increase in gene number followed by mutation may lead to organismal and functional complexity. In addition, genomes contain a large quantity of repetitive sequences, far in excess of that devoted to protein-coding genes (C-value paradox). At least 50–55% of the human genome is composed of repeat sequences, broadly composed of interspersed repeats, processed pseudogenes, simple sequence repeats, tandem repeats, and segmental duplications. Repeats have long been described as "junk", yet they actually play an important role in disease etiology, speciation, mutation and selection. These sequences may also shed light on chromosome structure and dynamics by reshaping the genome through rearrangements, creating entirely new genes and modulating the overall GC content.

Segmental duplications (also known as *low-copy repeat elements*) are a newly identified class of repetitive elements that consist of physically interspersed blocks of duplicated material in a genome. Duplicon is a specialized term applied to a segmental duplication whose extent of ancestral duplication is unambiguously delineated. In humans, these segments typically cluster in specific locations leading to structurally larger and more complex arrays that are later duplicated and rearranged into a mosaic patchwork architecture. Several of these clusters or nexi have been associated with the etiology of recurrent chromosomal rearrangements. The functional importance of these regions in genome evolution is only now beginning to become apparent.

2. Structural organization of segmental duplications in the human genome

Initial sequence analysis of the human genome has shown that ∼5–6% of the genome is composed of segmental duplications ranging in size from a few to

hundreds of kilobases, which are composed of a mosaic of duplicated segments originating from diverse areas of the genome (Cheung *et al*., 2001; Bailey *et al*., 2002a). The high degree of sequence identity (more than 60% of these duplications by mass show greater than 97% identity) suggest a recent origin. The first anecdotal reports on segmental duplications arose from routine physical mapping during the early phases of the Human Genome Project or as consequences of characterizing breakpoints associated with recurrent chromosomal structural rearrangements (Eichler, 1998; Inoue *et al*., 1999). On the basis of their distribution pattern, two types of segmental duplications may be distinguished. *Intrachromosomal duplications (chromosome-specific repeat regions (REPs) or low-copy repeat sequences (LCRs))* are genomic sequences interspersed along a single chromosome. On the other hand, segmental duplications located among nonhomologous chromosomes are termed *interchromosomal duplications* (*transchromosomal*). The amount of intrachromosomal and interchromosomal duplications varies dramatically among human chromosomes (Figure 1).

Several signature features distinguish intrachromosomal duplications, although finer details of the organization and distribution of subsequences in every chromosome vary. LCRs are often physically restricted to one chromosome and are situated in the proximal portions (within the first 10 Mb) of human euchromatic arms. Several chromosome-specific LCRs have been identified on a large number of chromosomes. Each block consists of smaller repeats (*duplicons*) that correspond to fragments of genes that originated from an ancestral locus. Most LCRs are relatively recent, as shown by their high range of sequence identity (97.5–99%), with variation reaching allelic levels or single-base changes. These interspersed intrachromosomal duplications predispose adjacent unique sequences to recurrent chromosomal structural rearrangements that are most often associated with diseases.

Interchromosomal duplications are physically biased to accumulate near heterochromatic regions (pericentromeric) and subtelomeric portions of chromosomes, possibly acting as a transition sequence between satellite repeat sequences and protein-coding sequences. Nearly half of all human chromosomes contain a 1–2-Mb zone of duplication extending from the satellite-repeat-containing centromere to the unique euchromatic regions. In the case of subtelomeric regions, blocks of interchromosomal duplications are usually situated within <100 kb of the telomeric T_2AG_3 tracts. A large number of partial- and whole-gene duplications has been characterized in detail. These segmental duplications share conserved exon-intron structure and have from 2 to 40 copies interspersed throughout the genome (Eichler, 2001). At least 30% of pericentromeric duplications originated from duplicatively transposed euchromatic regions (She *et al*., 2004a).

2.1. Pericentromeric duplications

Pericentromeric regions demarcate the transition between the heterochromatic satellite DNA at the centromere and the euchromatic gene-containing chromosome arm sequences. Such regions are sites of rapid evolutionary turnover, reduced gene expression, and suppressed genetic recombination. Directed mapping and sequencing of human pericentromeric regions reveal a preponderance of partial

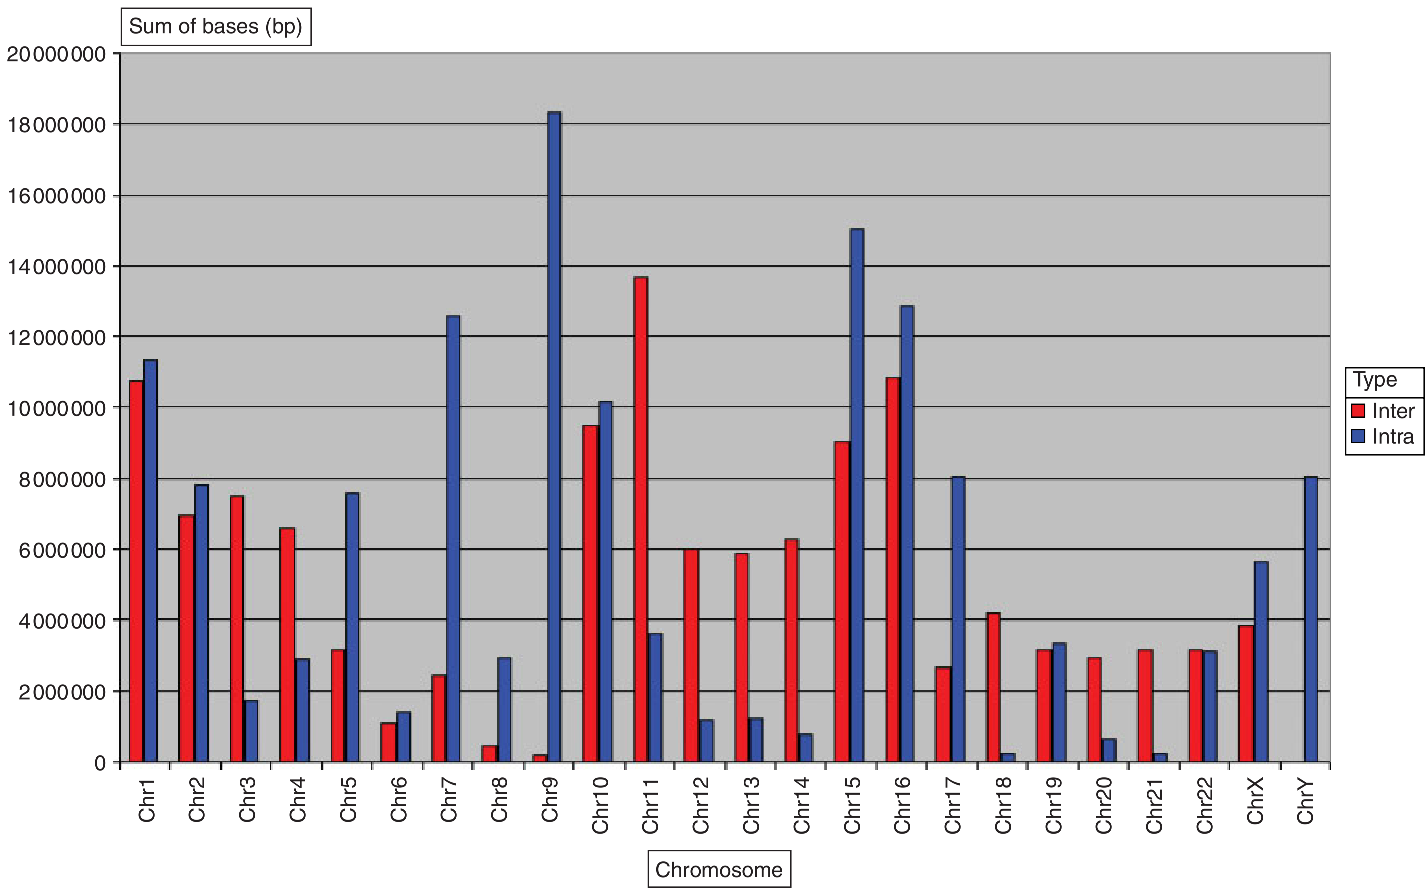

Figure 1 Segmental duplications in the human genome based on sequence identity and alignment length (>90%, >1 kb) of the finished human genome sequence (build35; May 2004). Inter- (red) and intra-chromosomal (blue) duplications vary per chromosome

gene duplications (Jackson *et al*., 1999; Loftus *et al*., 1999). Although the occurrence of mobile genetic elements and duplicated sequence within pericentromeric regions is a common property shared by distant species, the structure of the human genome appears to be unique in the proportion and extent of euchromatic blocks of duplications (Dunham *et al*., 1999; Hattori *et al*., 2000; Bailey *et al*., 2002b). Genome-wide assessment of segmental duplications revealed a sevenfold bias for duplications to map in these specific regions of the genome.

A proposed model of pericentromeric organization consists of two distinct domains (Guy *et al*., 2000): (1) a proximal domain that is satellite-rich, transcript-poor, and prone to interchromosomal duplication and (2) a distal domain that is satellite-poor and prone to intrachromosomal rearrangement. Similar tracts along the intrachromosomal duplications within the pericentromeric regions of chromosomes 21 and 22 have been reported (Orti *et al*., 1998; Edelmann *et al*., 1999; Ruault *et al*., 1999; Footz *et al*., 2001). An apparent exception to this two-domain model is that of KIAA0187, which had multiple rounds of pericentromeric duplications and dispersal through intrachromosomal rearrangements (Crosier *et al*., 2002). A fraction of these duplications show no evidence of an interstitial euchromatic origin and are now collectively termed pericentromeric interspersed repeats (PIRs), to distinguish them from duplicons of euchromatic origin (Horvath *et al*., 2003). An example is PIR4, a 49-kb element that localizes exclusively to more than half of all human pericentromeric regions. The frequent association of these elements with the boundaries of interspersed segmental duplications suggests that they may play a role in interchromosomal duplication and/or that they represent the original milieu wherein the first segmental duplications are duplicatively transposed.

2.2. *Subtelomeric duplications*

Subtelomeric regions immediately adjacent to terminal $(T_2AG_3)_n$ tracts are preferential sites (–three- to fourfold) for the accumulation of segmental duplications (Bailey *et al*., 2001). Genome-wide analysis of human subtelomeric regions (500 kb from the termini) found that ~10% of the region consisted of duplicated material located within the last 100 kb of the chromosomal arm (Riethman *et al*., 2004). The duplicated portions are composed of two distinct domains. The distal subdomain lies adjacent to the telomere and is composed of a mosaic of short segments of shared sequence homologies from many different chromosomes. These shared homologies are <2 kb in length and suggest the occurrence of frequent exchanges among all telomeres (Flint *et al*., 1997). The proximal subdomain is composed of much longer segments (10–40 kb) of higher sequence identity, which indicate a more recent origin. These recent duplications could be the result of unbalanced translocations occurring between telomeres during primate evolution.

3. Mechanisms of origin of segmental duplications

As opposed to whole-genome duplication, the mechanism(s) by which segmental duplications propagate within genomes are only beginning to be established.

Detailed characterization of segmental duplications have suggested that progenitor loci of these highly homologous segments most often occur outside the pericentromeric duplication zone (Regnier *et al*., 1997; Zimonjic *et al*., 1997; Horvath *et al*., 2001). Mechanisms involve duplicative transposition of apparently normal genomic DNA, often containing genes and smaller repetitive elements and range in length from <1 to 100 kb in length. Eichler and Horvath (Horvath *et al*., 2000; Eichler *et al*., 1997) proposed a two-step model for the dispersal of duplicated segments among multiple pericentromeric regions. The first step involves transposition seeding, wherein genomic segments from different chromosomal origins transposed to an ancestral pericentromeric region. An estimate for the time of occurrence for these events was ~5–15 million years ago, around the time of the divergence great-ape lineages. Multiple secondary events apparently duplicate larger blocks among pericentromeric regions of other nonhomologous chromosomes (Figure 2). These duplication events are more recent, and a few are restricted to the human lineage.

The mechanism for subtelomeric duplications likely differs from that observed in pericentromeric regions. Nonspecific, cryptic subtelomeric chromosomal rearrangements are known to occur frequently in humans, at a rate of 3–7.4% of patients with idiopathic mental retardation (Knight *et al*., 1997). During recent primate evolution, small unbalanced translocations may have occurred at a frequency that effectively contributed to the diversity of the subtelomeric regions through fixation. The sequencing analysis of the breakpoint sequences in ancestral subtelomeric regions supports this hypothesis (Martin *et al*., 2002), sharing strong yet discontinuous homology with ancestral copies at nonhomologous subtelomeric regions, as a result of sequence exchange among nonhomologous chromosomes during clustering of telomeres at the nuclear envelope (chromosomal bouquet formation). Segmental duplications at subtelomeric regions are thought to increase the gene copy number if functional genes are retained (Linardopoulou *et al*., 2001).

The mechanism by which intrachromosomal duplications have adopted an interspersed configuration within the human genome is unknown. Several studies however, point to Alu retroposons as playing a role in this process (Bailey *et al*., 2003; Babcock *et al*., 2003). Alu repeat sequences, particularly chimeric Alu repeats composed of two or more different subfamily sequence signatures, are enriched precisely at the boundaries of segmental duplications. This change supports an Alu–Alu recombination model for the origin of their interspersed configuration. Once interspersed segmental duplications have emerged, they are further propagated by nonallelic homologous recombination. A signature of such a recombination event is a change in copy number of sequence located between two segmental duplications. The rate of unequal crossing-over can rise dramatically in areas of tandemly repeated sequences. The activity of mobile elements and the nature of surrounding sequences influence the occurrence of duplications (Otto and Yong, 2002). Complex mechanisms have evolved to decrease the rate at which duplications establish within populations (Selker, 1999). Other general mechanisms that either silence duplicated sequences or degrade messenger RNA transcripts of duplicated genes are possibly present. These mechanisms have evolved as defense mechanisms to curb the proliferation and interference of transposable elements and dying duplication transcripts.

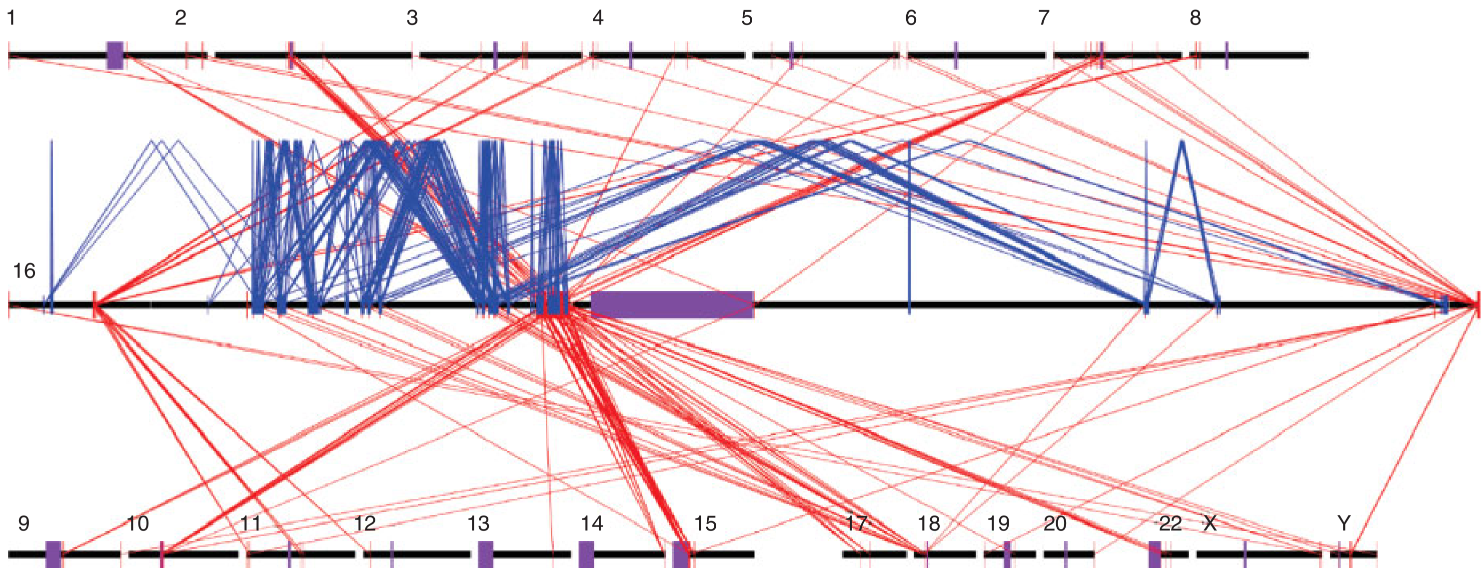

Figure 2 Recent segmental duplications on human chromosome 16. Large (>20 kb) highly similar (>90%) intrachromosomal (blue) and interchromosomal (red) segmental duplications are shown for chromosome 16. Chromosome 16 is magnified in scale relative to the other chromosomes. The intrachromosomal duplications shown may be sites of unequal homologous recombination resulting in large-scale rearrangements such as chromosomal region 16qh heteromorphisms. The centromere is colored purple. Cited from She *et al*. (2004b), **http://humanparalogy.gs.washington.edu/build35/chrom_cut.htm**

4. Screening tools for segmental duplications

Initially, identification and characterization of segmental duplications were based on anecdotal reports involving fluorescence in situ hybridization (FISH) probes hybridizing to unexpected multiple chromosomal sites or duplicated sequences existing at recurrent chromosomal breakpoints (Figure 3). While methods for screening mutations are well established, quantitative gene dosage measurements for larger (>100 bp) genomic regions may be underestimated (Armour *et al*., 2002). Computational, molecular, sequence, and cytogenetic methods, when used collectively, provide the most powerful assay to detect segmental duplications, with each method serving as a validation or complement to the other detection method. In certain laboratory settings, classical time-consuming methods such as Southern blot or other molecular tools screen for duplications and deletions. Recently, several new approaches have emerged that demonstrate high specificity and sensitivity in detecting recent duplications.

Computational methods provide a rapid means to detect duplicated DNA at a genome-wide level. In principle, it involves identification and extraction of high-copy repeats from the genomic sequence using RepeatMasker (Smit and Green, **http://repeatmasker.genome.washington.edu**), searching for similarities in the remaining unique sequences by BLAST (Altschul *et al*., 1997), reinserting repeats

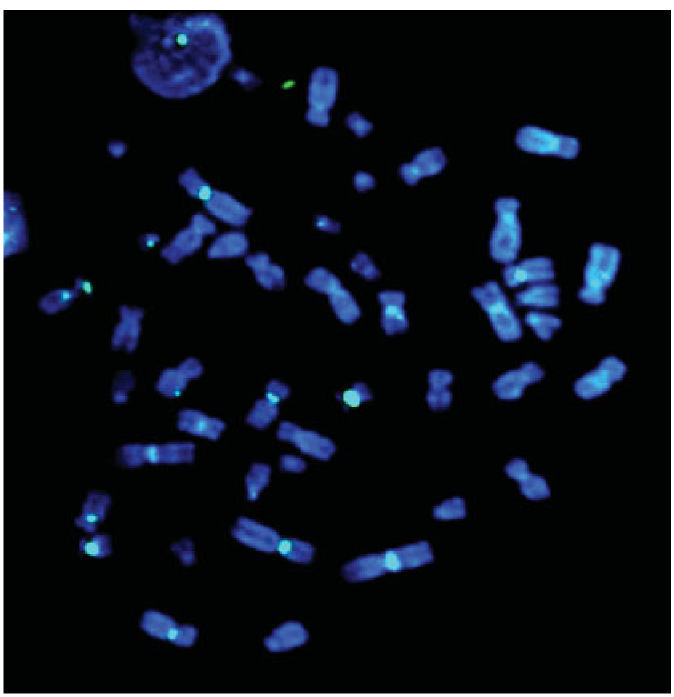

Figure 3 Localization of human chromosome 16p11-specific clone AC002037 in a metaphase chromosome spread shows multiple hybridization signals on chromosomal regions 2p11, 10p11, and 22q11

to generate pairwise alignments, heuristic trimming of the ends of the alignments, and generating global alignments with statistics (Bailey *et al*., 2001; Venter *et al*., 2001). Some selection criteria have been developed to minimize false-positives. Size ≥1 kb and sequence identity of ≥90% thresholds typically detect duplication events within the last 35 million years of primate evolution. Junction analyses also provide valuable hints on sequence exchange mechanisms between specific nonhomologous regions in the genome (Mefford *et al*., 2001; Mefford and Trask, 2002). More recently, assembly-independent approaches have identified potential duplications within genome sequence (Bailey *et al*., 2004a).

FISH has served as a straightforward experimental system for physically mapping DNA probes to metaphase chromosomes using antibody-based staining procedures. Probes generated from YACs, BACs, and PACs are either labeled directly using fluorochrome-conjugated nucleotides (e.g., fluorescein-dUTP; Cy5-dUTP) or indirectly using reporter molecules (e.g., biotin-dUTP; digoxigenin-dUTP) by nick-translation, random priming, or other molecular genetic techniques. FISH has provided a mechanism in determining the presence, number, and distinct location (in situ) of genetic material for characterization of intra- and interchromosomal rearrangements, regardless of their complexity. FISH fills the gap between molecular biology and chromosome banding analysis, resulting in a marked progress in cytogenetics research (for review, see (Trask, 2002)). Comparative mapping using region-specific probes has facilitated the identification of subchromosomal homologies, detailed reconstruction of genomic changes, and map evolutionary breakpoint regions in closely related species (Conte *et al*., 1998; Samonte *et al*., 1998). Advances in microscopy and signal detection hardware have allowed the low light level produced by FISH signals to be recorded and analyzed with increasing sensitivity. This 20-year-old technology has been most extensively used in the confirmation of segmental duplications (Rosenberg *et al*., 2001; Der-Sarkissian *et al*., 2002; Ravise *et al*., 2003).

A modified version of FISH that provides a much higher resolution is fibreFISH, which collectively refers to all hybridizations performed on released chromatin or DNA fiber, including chromatin FISH, halo FISH, visual mapping, direct visual hybridization (DIRVISH), and molecular combing. The degree of condensation is much less than metaphase chromosomes and interphase chromatin and is effective in the establishment of sequence order of BAC contigs, mapping ESTs, estimating and filling gaps in sequence-ready maps, and determining copy number of large-scale segments in the human genome (Ziolkowski *et al*., 2003; Pagel *et al*., 2004). FibreFISH is also used in medical genetics for the study of gene amplification, deletion and translocation, as well as the correlation of gene numbers with clinical phenotypes in diseases caused by additional copy numbers of genes. For segmental duplications, fibreFISH is most valuable in confirmation of closely spaced tandem duplicates and characterization of copy number variants in these regions.

Microarray-based comparative genomic hybridization (array-CGH or matrix-CGH) is a relatively new and revolutionary platform for high-resolution detection of DNA copy number aberrations. The improvement of this technique over a short time has provided many applications in research and high-throughput diagnostics. CGH was originally developed for genome-wide analysis of copy number imbalances

by cohybridization of differentially labeled whole genomic test and control DNA in a ratio of 1:1 on normal control metaphase spreads under conditions of in situ suppression hybridization (CISS). The resulting fluorescence intensity ratio is quantified by an imaging software that calculates a copy-number or molecular karyotype of the entire genome. However, the use of metaphase chromosomes provided low resolution (5–10 Mb for deletions and 2 Mb for duplications). The resolution of CGH improved by using arrayed subsets of genomic clones (BACs, PACs, and cosmids) and cDNA. Initial testing of the array-CGH focused on chromosome-wide screening of gene duplications and deletions and subsequently moved on to genome-wide scans and specific chromosomal regions. Resolution of CGH-arrays have improved over time, with an average resolution of 1.3 Mb (Fritz *et al*., 2002; Wilhelm *et al*., 2002). A recent genomic array format employing PCR repeat-free and nonredundant sequences operates with a resolution of ~23 kb (Mantripragada *et al*., 2003). Segmental duplications vary in size and degree of sequence identity, and hence the ability to detect gene dosage changes in these regions has been questioned. There is currently a limited yet promising number of investigations on these genomic regions (Locke *et al*., 2004; Shaw *et al*., 2004). Array-CGH has the power to discriminate between one and two DNA copies, as well as to detect homozygous deletions and unbalanced translocations. However, signal-to-noise ratio remains as a limiting factor in the reliability of microarray data. Although array-CGH holds considerable promise to revolutionize cytogenetics, the technology is not capable of detecting low-level mosaicism, balanced rearrangements or inversions, and for the time being, can only be seen as a supplementing technique for the examination of chromosome aberrations (Iafrate *et al*., 2004).

5. Role of duplications in human disease

Several studies have demonstrated that closely located segmental duplications are one of the factors predisposing to the occurrence of genomic disorders, mainly by acting as highly unstable hotspots for chromosomal rearrangements (Ji *et al*., 2000; Emanuel and Shaikh, 2001). Such recurrent chromosomal changes result in dosage imbalances caused by deletion or duplication of genes that lie within the rearranged segments (*segmental aneusomy*). Gene dosage imbalances further result in misalignment and nonallelic homologous recombination between segmental duplications. The term *genomic disorder* was coined to designate diseases presenting with gene dosage etiologies (Lupski *et al*., 1998). A subset of these disorders is presented in Table 1. The most common rearrangements in the human genome are the deletions associated with DiGeorge syndrome (DGS; OMIM 188400), velocardiofacial syndrome (VCFS; OMIM 192430), and conotruncal anomaly face syndrome (CAFS; OMIM 217095). The repeat units involved with deletions are usually small and retain the same orientation on the same chromosome, leading to slipped pairing and unequal crossing-over in meiosis. Tandem duplication of DNA can directly lead (through dosage effects) or indirectly (through subsequent microdeletion) to clinical phenotypes, including velocardiofacial syndrome (Edelmann *et al*., 1999) and Prader Willi/Angelman

Table 1 Examples of low-copy repeats (LCRs) associated with genomic disorders

Chromosomal localization	LCR name	Size of LCR	Associated genomic disorder	Size and type of rearrangement
7q11.23		320 kb	Williams–Beuren syndrome	1.6-Mb deletion
8p23	REPD	~1.3 Mb		~4.7-Mb inversion
	REPP	~0.4 Mb		
8q21	CYP11B1/2	10 kb	Hypertension?	Duplication
15q11-14	LCR15/HERC2	15 kb	Prader–Willi or Angelman's syndrome (PWS, AS)	4-Mb deletion
17p11.1	SMS-REP	200 kb	Smith–Magenis syndrome	3.7-Mb deletion
17p12	CMT1A-REP	24 kb	Charcot-Marie-Tooth disease type 1A (CMT1A) and hereditary neuropathy with liability to pressure palsy (HNPP)	1.4-Mb duplication/ deletion
21q21.3 → qter		550 kb	Mild developmental delay and mild dysmorphic features	15.5-Mb deletion
22q11	LCR22	225–400 kb	Velocardiofacial syndrome/DiGeorge syndrome, der(22) syndrome, and cat-eye syndrome	3-Mb deletion
Xq28	RCP, GCP	39 kb	Color blindness	Deletion
Yq11.2	AZFa, AZFc	229 kb	Male infertility	800-kb deletion

syndromes (Christian *et al*., 1999). In addition, large tracts of sequence frequently transpose into pericentromeric locations and distribute between nonhomologous chromosomes in a centromere-specific manner (Eichler *et al*., 1999). Construction of a chromosomal duplication map of malformations (Brewer *et al*., 1999) showed that half of the bands associated with duplications or deletions are pericentromeric, representing triplo- and haplolethal regions of the human genome. In addition, hyperploidy is better tolerated than hypoploidy in the human genome, with phenotypes associated with deletions more severe than those associated with duplications. Statistical analyses used to create cytogenetic duplication and deletion maps have shown that breakpoints involved in duplications are not randomly distributed, but instead, cluster within certain chromosome regions. Such maps may be useful in obviating the need for whole-genome scans as a first approach to identify disease genes.

The presence of heterozygous inversions at regions flanked by the segmental duplications may also be predisposed to further rearrangement (Gimelli *et al*., 2003). These submicroscopic inversions would interfere with the normal homologous synapses and promote misalignment and abnormal recombination. Moreover, inversions are a common cryptic feature of unstable chromosomal regions in the general population, and can thus be considered genomic polymorphisms (Samonte *et al*., 1996; Osborne *et al*., 2001). Rearrangements involving duplicatively transposed genomic sequences have been termed segmental polymorphisms, structural variants, large copy-number variants (LCV) or copy-number polymorphisms (CNPs). The characterization of such variation at the sequence level will require unprecedented high-throughput screening at a genome-wide level not readily achieved by current technology.

6. Segmental duplications and primate genome evolution

Previous decades of comparative analysis of proteins and chromosomes in higher primates and humans have shown striking similarities. Cytogenetically, hominoid chromosomes only differ by some gross chromosomal rearrangements such as peri- and paracentric inversions, reciprocal translocations, band insertions, and chromosome fusions. Inversions were the most common rearrangements in the great ape and human karyotypes, while translocations, Robertsonian fusions, and fissions, appeared to be more common in lesser apes and lower primates. On the basis of the limits of resolution of chromosome banding and painting techniques, interchromosomal rearrangements occur minimally, while intrachromosomal rearrangements (inversions, transpositions) needed further delineation of chromosome subregions. Finer-detailed karyotypic differences were later described by ZOO-FISH mapping.

The identification of highly homologous segmental duplications in the human genome has triggered comparative screening of these large-scale segments in closely related species (Table 2). The role of segmental duplications as one of the major driving forces in primate genome evolution has recently been reviewed (Samonte and Eichler, 2002). Segmental duplications appear to be an ongoing process that has been active throughout recent primate evolution, with a growing list of primate evolutionary chromosomal rearrangements wherein segmental duplications have been involved or have been noted within the proximity of these events (Stankiewicz *et al*., 2001; Dennehey *et al*., 2004). Most of these analyses employed a combination of molecular biology, in silico, and cytogenetic techniques in characterizing paralogous copies in the specific regions of the genomes. Comparative primate FISH mapping validated genomic sequence movements associated with intrachromosomal rearrangements by determining the physical location and order of clones in chromosomal regions earlier grossly described by classical G-banding techniques. An example showing the progressive characterization of a chromosome rearrangement in the course of primate genome evolution is the telomeric fusion described by Yunis and Prakash (1982), involving integration of two ancestral chromosomes in a head-to-head fashion to form human chromosome 2. Subsequent inactivation of one of the two original chromosomes

Table 2 Human–great ape evolutionary chromosomal rearrangements associated with segmental duplications

Human chromosomal site involved	Estimated time of occurrence (million years ago, mya)	Size of duplicated region	Duplicons involved	Other duplications	References
2q13–2q14.1	<6 mya	>600 kb		9pter, 9p11.2, 9q13	Fan *et al*. 2002
15q11–q13	2–5 mya	~600 kb	LCR15, GLP, CHRNA7		Locke *et al*. 2003a
18q11	<6 mya	19 kb		18p11	Dennehey *et al*. 2004; Goidts *et al*. 2004
5q13.3 and 17p12	<8 mya		LCR17pA, LCR17pB		Stankiewicz *et al*. 2001

resulted in 46 chromosomes in the humans, whereas chimpanzee, gorilla, and orangutan have 48 chromosomes. The telomeric fusion was later confirmed by comparative FISH-mapping (Luke and Verma, 1992; Wienberg *et al*., 1994; Ijdo *et al*., 1991). It has recently been shown that >600 kb of sequence surrounding the fusion site consisted of highly homologous (96–99% sequence identity) sequence blocks that had been duplicated to several subtelomeric and pericentromeric regions of nonhomologous chromosomes prior to the fusion event (Fan *et al*., 2002). Segmental duplications may have possibly influenced the fusion of these two ancestral chromosomes producing the current architecture of human chromosome 2.

Large-scale differences among primate genomes have been grossly underestimated by karyotype analyses, and it has been suggested that copy number differences and qualitative differences in their distribution may be more significant for primate genome evolution than previously anticipated. In silico and comparative FISH mapping of a set of human chromosome 5–specific clones on several primate species showed an accumulation of segmental duplications in euchromatic regions and preferential duplicative transposition from the heterochromatic region of human chromosome 5 (Courseaux *et al*., 2003). The CMT1A-REP repeat, a pericentromeric segmental duplication responsible for a 1.5-Mb duplication and deletion associated with the Charcot-Marie-Tooth disease type 1A (CMT1A) and hereditary neuropathy with liability to pressure palsies (HNPP), was present as a single copy in several primates screened by comparative FISH mapping, except for chimpanzees. This chimpanzee-specific duplication of an ancestral sequence occurred during primate evolution (Keller *et al*., 1999). A human-specific pericentric inversion in chromosome region 15q11-q13 characterized by comparative FISH mapping and sequence analyses showed involvement of at least two duplicons, CHRNA7 and GLP/LCR15 (Locke *et al*., 2003a).

As more low-copy repeat-induced chromosomal rearrangements are identified, the notion that genome evolution is influenced by both macro- as well as microrearrangements is strengthened. Comparison of human and great-ape genomes using array comparative genomic hybridization (array-CGH) identified 63 sites of putative copy-number variation in both euchromatic and heterochromatic regions (Locke *et al*., 2003b). Examination of only 12% of the genome showed large-scale differences of hundreds of kilobases, suggesting that microrearrangements are frequent between humans and great apes. Moreover, nearly 50% of validated copy-number variation mapped to regions of segmental duplications strongly suggest that a nonrandom distribution of such events. A recent genome-wide gene-based screen for gene duplication across five hominoid species has indicated that most of the copy number changes occurred in the past 15 million years, with the human species showing the most pronounced expansions (Fortna *et al*., 2004).

Paralogous sequences have consistently reshaped the primate genome, creating putative mosaic genes and causing rearrangements that have affected genomic stability. Regions that were involved in independent chromosome rearrangements during primate evolution were also prone to intragenomic duplication. One plausible explanation is that large-scale rearrangements and cytogenetically cryptic deletions and duplications result from the same genomic turnover processes.

7. Duplications in other species

The availability of a number of eukaryotic genome sequences makes it possible to examine patterns and types of gene duplication that have structured genomes resulting in species-specific genome architecture. As confirmed from comparative primate analyses, both micro- and macroarrangements have been the major force in primate genome evolution, with mammalian genomes described as mosaics composed of rearrangement-prone fragile regions and conserved solid regions (Pevzner and Tesler, 2003). Assessment of mouse and rat genome sequences for content, structure, and distribution of segmental duplications have provided the opportunity to compare the nature and pattern of these highly homologous sequences and to determine their role in shaping the mammalian genome. Such comparisons to orthologous segments in other genomes would also provide a means for establishing the relative order and timing of the duplications. Interestingly, both rodent genomes (mouse, 1.7–2%; rat, 2.92%) showed reduced amounts of segmental duplications than that of the human genome (5–6%) and instead, tandem or clustered duplications were more frequent. Such estimates are only preliminary, especially in light of the fact that these regions of the euchromatin are among the last to be adequately resolved (Eichler *et al*., 2004). Thus, the structure and precise composition of segmental duplications within the mouse and rat genomes remain to be determined.

Pericentromeric duplications are observed to be a common feature in the mouse and rat genomes (Tuzun, 2004; Bailey *et al*., 2004b; Thomas, 2003). In the mouse, this similar mosaic architecture of sequence modules generates chimeric transcripts. However, unlike the human genome, insertions and deletions within duplicated segments are more common in the mouse, while short repeated sequences flanking duplicons appear to be absent in the mouse genome. On the basis of the estimates of sequence divergence in the mouse genome, it appears that segmental duplications are relatively of recent origin (3–7 million years ago) and have occurred at several distinct periods. A model for the evolution of the pericentromeric regions of mouse chromosomes 5 and 6 have been proposed to involve fission of an ancestral chromosome, followed by the repair on each side of the break and creation of two new centromeres and chromosomes. Since all mammals as well as the chicken genome show proximity of segmental duplications to centromeres, it is likely that unusual aspects of centromere biology, including recombination differences and/or increased rates of interchromosomal gene conversion, play an important role in the biased distribution.

8. Summary

The human genome has been changing through a variety of mutational processes. Recent segmental duplication is one such process that appears to be relevant to our understanding of both human genome evolution and genetic disease. Assessment of other eukaryotic genomes will provide a broader view of the relationship of duplications to mechanisms of chromosome evolution and gene innovation. Understanding the origin and propagation of segmental duplications will provide fundamental insight into how genes and genomes change during the course of time.

Noncoding RNAs in mammals

Timothy Ravasi and David A. Hume
University of Queensland, Queensland, Australia

1. Introduction

As the genome-sequencing revolution has progressed through more complex organisms, the first outcome of each new genome sequence has been an estimated gene count. What appears to be an obsession with enumeration has largely ignored the question of the definition of a gene. From a geneticist's viewpoint, a gene is a unit of function that is defined by a mutant phenotype. On that basis, a gene can be defined as the minimal segment of DNA that is able to complement a mutant phenotype. In prokaryotes, and simple eukaryotes, the boundaries of a gene, a segment of DNA that must include the control elements in order to provide complete complementation, are relatively easy to define. As we have climbed up the level of genomic complexity to plants and animals, this definition of a gene has become untenable. Saturation mutagenesis of a mammalian genome is clearly a long way off and were it possible, analysis of the precise nature of each lethal phenotype is a major project and nonlethal mutations with no apparent phenotype present even greater challenges. As a consequence, genome scientists have accepted the de facto definition that a gene is the segment of DNA that encodes a protein; and in doing so have accepted the view that the only functional output of the genome (since gene is a functional definition) is a protein. Indeed, a focused effort by the NIH to produce a mammalian gene collection is directed exclusively to the identification of cDNAs that contain a complete open-reading frame (Baross *et al*., 2004), and a recent large-scale expression dataset in mouse and human focuses solely on protein-coding transcripts (Su *et al*., 2004). Even this approach leaves aside the major impact of alternative splicing on the proteome, and begs the question of whether a distinct cDNA encoding a different form of a protein, controlled by a distinct promoter and expressed in a distinct tissue, constitutes a separate gene.

It was recognized at a very early stage in genome-sequencing projects that the sequence could not be adequately annotated without extensive analysis of the transcriptome, the transcriptional output of the genome. There have been several different approaches to the analysis of transcriptional output. High-throughput approaches such as expressed sequence tag (EST) sequencing, and SAGE, followed by computational assembly into contigs (e.g., in UniGene/TIGR Gene Index) have generated large estimates of the number of separate transcripts that can be

encoded by a mammalian genome (Liang *et al*., 2000; Quackenbush *et al*., 2000; Quackenbush *et al*., 2001; Fahrenkrug *et al*., 2002; Lee *et al*., 2002; Sonstegard *et al*., 2002). The outputs have been useful in identifying putative exons in genome sequence, but do not help in identifying genuine contiguous transcripts, since one can have no confidence that the segments brought together in silico actually coexist in a real transcript. In part to deal with this problem, and in part to generate full-length cDNA physical clones, a number of groups attacked the task of isolating and sequencing a complete collection of the cDNAs representing the mammalian transcriptome (Kawai *et al*., 2001; Okazaki *et al*., 2002; Dalla *et al*., 2003; Ota *et al*., 2004). This is a greater challenge than the genome, since each individual cDNA must be generated from a particular tissue source of mRNA. Even taking account of the uncertainties with annotating genuine coding regions within the sequenced cDNAs, and problems with cloning artifacts leading to cDNA truncation at the 5′ or 3′ end, it became evident from the analysis of the first large sets (Kawai *et al*., 2001) that even amongst polyadenylated "mRNAs" there is a very significant component of full-length transcripts that do not encode a protein. As the systematic cloning of full-length cDNAs has progressed, and focused on less-abundant transcripts, the size of the validated noncoding RNA component of the transcriptome has continued to grow (Okazaki *et al*., 2002; Shabalina and Spiridonov, 2004). The existence of noncoding RNAs has been further validated with the appearance of genome-tiling microarrays (Kampa *et al*., 2004; Bertone *et al*., 2004). The isolated, or predicted, full-length cDNAs have focused mainly on polyA-plus mRNA and the size of transcripts that have been isolated and fully sequenced has been constrained by the ability to generate full-length cDNAs, to clone them into sequencing vectors, and to sequence them. A recent study using high-density genome-tiling arrays, and separately analyzing nuclear and cytoplasmic RNA, and polyA-plus and polyA-minus RNA populations, has revealed that up to 14.6% of the genome is transcribed in a single human cell type (Gingeras T, personal communication).

What does it all mean? Is the "junk DNA" transcribed into "junk RNA", or do all these transcriptional outputs of the genome actually have a function? In this review, we will present an analysis of the possible classes of noncoding RNAs that have been identified, overview evidence that their expression is regulated, and discuss some of the possible functions. The review will focus especially on the data from the mouse, the mammalian species in which the transcriptome has been most extensively sampled.

2. How many noncoding RNAs are there?

For the purpose of this review, we will take as a given that a very large fraction of the animal genome, from drosophila to man, is actively transcribed, in many cases from both strands. (Eddy, 2001; Shabalina and Spiridonov, 2004; Kampa *et al*., 2004; Stolc *et al*., 2004; Bertone *et al*., 2004). Combined with full-length and EST sequencing efforts, the evidence indicates that 50% or more of the transcripts generated do not contain an open-reading frame that is likely to be translated into a protein. Whereas the size of the predicted protein-coding transcriptome is

unlikely to grow a great deal beyond the current estimate of 30 000 “genes” in mammals, since the size can be inferred with some confidence from comparisons of completed genomes, the size of the predicted ncRNA (noncoding RNA) component will probably continue to grow as the depth of coverage increases. The ncRNAs that have been identified are generally less abundant than protein-coding RNAs. In a recent global analysis in drosophila using genome-tiling arrays (Stolc *et al*., 2004), protein-coding transcripts and genes associated with a known mutant phenotype were more highly expressed and 76% were differentially expressed at specific developmental stages. Conversely, putative ncRNAs, whether derived from intergenic or intragenic regions, were generally expressed at lower levels and only 15% showed developmental regulation. This observation cannot imply that any putative ncRNA lacks a function. A single molecule of RNA could be all that is required to act in cis in control of transcription. It says simply that they tend to be less abundant, and more will be identified as one digs deeper into expressed sequences. However, it does suggest that with depth of coverage one can drift into the territory of what skeptics would call “transcriptional noise”, at the extreme where the RNA is actually present at less than copy per cell but is still detectable.

Although in situ transcription assays are possible, and might eventually be used to complement array-based approaches, the detection of the transcriptional output of the genome generally requires the synthesis of cDNA as an intermediate, either for generation of probes to use in microarrays, or for cloning and sequencing. In undertaking any such analysis, the outcome is dependent upon the method used to purify the RNA, and the approach to cDNA synthesis. If the intent is to identify mature, processed transcripts that find their way into the cytoplasm, as opposed to primary nuclear transcripts, they can be enriched by stringent separation of cytoplasmic from nuclear RNA, and by purification using oligo-dT affinity chromatography to capture polyadenylated mRNA. Separation of nucleus from cytoplasm cannot be 100% efficient, especially from solid tissues rather than cell lines, and one can have no confidence of excluding leakage of nuclear transcripts into the “cytoplasm” when cells are lysed. If there is any systematic attempt to normalize the mRNA pool by subtraction to reduce the incidence of abundant transcripts, the inevitable consequence is that nuclear “contamination” will be enriched in the process.

The issue of nuclear contamination raises the issue of the extent of representation of partially processed nuclear RNAs in the putative ncRNA pool, and in turn whether these should be excluded from the ncRNA definition. There is a tacit assumption in all analysis of the transcriptome that intronic sequences are removed from the primary transcript by splicing, rapidly decay, and are unlikely to make a significant contribution to detectable outputs of the transcriptome. By extension, spliced introns per se are presumed to have no function and are not considered in analyzing the scale of the transcriptome. However, this assumption has seldom been systematically tested. In a landmark study, Clement *et al*. (2001) detected all three spliced introns from the coding region of the Pem homeobox gene in total RNA, and found that the half-lives of these Pem introns ranged from 9 to 29 min, which is in the same range as short-lived mRNAs such as those encoding c-fos and c-myc. Even more challenging to the prevailing dogma, all three of the spliced Pem introns were present in the cytoplasmic fraction. Although introns are regarded generally

as junk, these findings provide some support to the view that subsets of intron-derived RNAs excised by splicing can accumulate to significant levels, and could form part of a transcriptional control network (Mattick, 2001). A detailed study of the imprinted GNAS imprinted locus in the mouse also confirms that a number of transcripts with retained introns accumulate, and their expression is selectively controlled from one or other selectively imprinted parental allele (Holmes *et al*., 2003). If subsets of spliced introns or partly processed (or partly degraded) primary transcripts do accumulate selectively in the nucleus or cytoplasm, they will have been sampled only to a limited extent in transcriptome analysis based upon oligo-dT purification or priming, since this will sample only those that fortuitously include an A-rich string. Furthermore, they will not contain a consensus polyadenylation sequence nor will they be flanked by a classical promoter. The set of putative ncRNAs in the RIKEN mouse transcriptome set certainly contains a substantial component of such transcripts, which are routinely annotated as "immature". But where they have been tested, they appear to be reproducibly represented in purified RNA pools, and are therefore unlikely to represent fortuitous cloning of a partially spliced primary RNA.

Leaving aside the contribution of intron-derived RNAs to the detected transcriptome, at least some of the ncRNAs represented in cDNA collections and ESTs probably arise from the incomplete capture of a genuine full-length cDNA that lacks the complete open-reading frame. Even with the technical advances in full-length cDNA synthesis and capture of the 5′ end, the generation of a full-length cDNA requires reverse transcriptase to initiate at the 3′ end, commonly from an oligo-dT primer, and to extend through secondary structures in the RNA to a genuine 5′ end. On the basis of the capture of full-length coding regions of known protein-coding transcripts, the best outcomes for capture of the 5′ end are in the range of 70–80% full length. That is, the 5′ end of 70–80% of cDNAs in the best case represents the genuine transcription start site. Subsets of putative ncRNAs, lacking a predicted CDS, are annotated as "partial" based upon sequence overlap with another longer cDNA, or with an EST assembly. In no case can this be considered definitive. A subset of these ncRNAs with apparently truncated 5′ ends arise from internal promoters, and we cannot infer that they have no function solely because they lack the ORF of the corresponding "full-length" transcript.

Recognition of the potential "artifacts" associated with cytoplasmic RNA purification and cDNA production leads annotators to try to subdivide the putative ncRNAs based upon other features. A sizable subset of the RIKEN full-length mouse transcripts annotated as noncoding are bounded by consensus polyadenylation sequences at the 3′ end, and by consensus promoter regions at the 5′ end (e.g., CpG islands). These ncRNA are considered as mRNA-like, and this set contains many of the known functional ncRNAs (Numata *et al*., 2003). Unfortunately, the absence of these features says nothing about whether a putative ncRNA is "real" or a cloning artifact. We know so little about the function and regulation of ncRNAs that we cannot exclude the possibility that they are not capped in a conventional manner (e.g., like rRNAs), or that they utilize alternative transcriptional termination mechanisms (Eddy, 2001). If the ncRNAs that lack these conventional mRNA-like features prove also to be genuine transcriptional outputs, then their representation

in current cDNA collections will again be very low, since the current strategies for cDNA cloning are designed to exclude them.

In overview, our current knowledge does not permit us to distinguish cloning artifact from possible ncRNA based upon sequence analysis. However, many of the putative ncRNAs are strongly supported by expression analysis. In a recent study (Ravasi *et al*., 2005), we showed using RT-PCR, Northern blots, and microarray analysis that the large majority of the ncRNAs in the RIKEN clone collection are indeed reproducibly expressed, and many show tissue-specific expression. A subset is acutely regulated in macrophages stimulated with lipolysaccharide (LPS) (Ravasi *et al*., 2005), and the promoters directing expression of these transcripts show features in common with the promoters of LPS-stimulated protein-coding genes (unpublished).

If some of the existing putative cloned noncoding cDNAs are artifacts, or the corresponding transcripts are expressed as such low levels as to be best classified as transcriptional noise, the functional ncRNA output of the mammalian genome may be lower than what the current figures suggest. The expression analysis suggests this is not the case, and the genome-tiling data supports the view, supported by all the arguments above, that the number of ncRNAs encoded reproducibly by a mammalian transcriptome is actually very much larger than the current estimates.

3. The functions of noncoding RNAs

3.1. Mutations

It is inherently impossible to prove the absence of function, but skeptics about the function of ncRNA point to the absence of phenotypes associated with mutations. The number of non-protein-coding RNAs that have been functionally validated by mutagenesis screens in any eukaryote is small. The specific examples associated with mammalian imprinting will be discussed below. There are two well-cited examples in humans of genetic diseases associated specifically with loss of a noncoding RNA but these are actually RNA components of functional complexes (Eddy, 2001; Shabalina and Spiridonov, 2004). Conversely, in the ROSA-26 locus in mice, there are two highly expressed ncRNA transcripts convergent with a protein-coding transcript. Homozygous mutations of the ROSA-26 selectively ablates both ncRNAs, and mutants are born at less than the expected Mendelian ration, but there is no other phenotype evident, not even altered expression of the convergent-coding transcript (Zambrowicz *et al*., 1997). The majority of natural or chemically induced mutagenesis in mammals causes point mutations or deletions. A single deletion or mutation can, of course, radically disrupt protein-coding capacity of the encoded transcript but might have much less effect on the function of a ncRNA (Eddy, 2001). If ncRNAs do have a function, additional evidence that it does not require stringent sequence conservation comes from the fact that the large majority of identified ncRNAs are weakly conserved between mammalian species (Numata *et al*., 2003). So, function is likely to be inferred only by complete ablation of the transcript. In organisms such as drosophila, which also

produce many ncRNAs, the major approach to mutagenesis is P-element transposon insertion, yet even in this organism few phenotypes have been associated with ablation of an ncRNA. Given the possibility of high-throughput RNAi screens in this species (Boutros *et al*., 2004), it will certainly be feasible in future to assess whether any putative ncRNAs have nonredundant functions. Redundancy is obviously a secondary question. Many protein-coding genes, especially those that form part of multigene families, are redundant inasmuch as mutation has no apparent phenotype. Without knowing their functions, we cannot eliminate the possibility that ncRNAs form families containing short functional motifs, or with interdependent regulation/compensation, so that no single ablation abolishes the function of the ncRNA family. Support for this view comes from a recent global clustering analysis of putative ncRNA molecules, evocatively entitled "into the heart of darkness" (Bejerano *et al*., 2004). This study of the human genome identified 12 000 nonsingleton clusters dense in significant sequence similarities.

3.2. The transcriptional noise view

A genome-tiling analysis of sites on human chromosomes bound by the general transcription factor Sp1 revealed numerous binding sites associated with the apparent initiation of noncoding RNAs (Kampa *et al*., 2004). Sp1 sites are associated with transcription initiation in TATA-less promoters, and a significant proportion of the ncRNAs in the mouse transcriptome originate from CpG islands (Numata *et al*., 2003). A skeptical view is that the CG-rich Sp1 recognition motif occurs frequently in genomic sequence in CpG islands and with some measure of randomness binds Sp1 and initiates the production of transcripts that represent background noise; in essence, just a reflection of the large size of the mammalian genome. An extension of this view is that many such sites occur within Alu repeats, and other ancestral retrotransposons that retain cryptic, or low level, intrinsic promoter activity.

True randomness is an unlikely scenario, because the majorities of Sp1 sites in genomic DNA, and of repeat elements, are assembled into inactive chromatin, and are methylated and/or inaccessible to transcription factor binding. Transcriptionally active regions of the genome are associated with acetylated histones, and are sensitive to digestion by DNase (DNase hypersensitive sites). A more plausible origin for many ncRNAs lies within specific enhancers that occur in 5′ or 3′ flanking regions or within the introns of most protein-coding "genes". These sequences are commonly conserved across mammalian species. There are numerous examples in the literature of enhancers acting as promoters, not surprisingly since they commonly bind the same sets of transcriptional activators as conventional promoters. For example, in the globin locus, a distal enhancer initiates transcription of a long transcript that extends through to its downstream promoter elements. Ling *et al*. (2004) showed recently that interruption of this transcript greatly reduces the activity of the linked downstream promoter. Cook (2003) put forward the interesting idea that transcription arising from enhancers acts to focus the enhancer and linked promoter regions into the active "transcription factories" within the nucleus, thereby facilitating the looping out of intervening sequences

and concentrating the transcription regulators around the transcription start site of the target promoter. Since enhancers commonly bind tissue-restricted transcription factors, the production of ncRNAs from such elements will display the same regulation as the transcripts that are controlled by the enhancer. In the global study of drosophila transcription, expression of putative ncRNAs correlates significantly with expression of the closest annotated exons (Stolc *et al*., 2004). In some cases, this may mean that the putative ncRNAs are simply unannotated exons of the adjacent gene. But equally, this pattern would occur if the enhancers that control expression of the adjacent genes also direct transcription of ncRNAs.

4. Possible functions of ncRNAs

Broadly speaking, ncRNAs might function as catalytic RNAs, through their ability to base-pair with DNA or RNA of related sequence (or through triplex formation), or by binding to proteins. Some of the proposed and validated functions are discussed below. We will not deal in detail here with microRNAs and RNA interference, which has been reviewed elsewhere (Eddy, 2001; Mallory and Vaucheret, 2004).

4.1. Imprinting, silencing, and activation: cis-acting effects of ncRNAs

The archetypal functional ncRNA in mammals is *xist*, which functions in cis to initiate global chromatin remodeling and silencing on the X-chromosome (Brown and Chow, 2003; Ganesan *et al*., 2004). Precisely how this function is mediated remains unclear. The cis-acting function of ncRNAs in gene silencing is also evident in a number of imprinted loci. The best-characterized example is the IGF2R receptor locus, in which a very large antisense transcript is implicated in allele-specific transcription control. Ablation of the promoter driving this transcript (AIR) was found to abolish imprinting and in a separate transgenic manipulation, the role of antisense per se was excluded by directing production of AIR from an alternative promoter that does not overlap the IGF2R promoter (Sleutels *et al*., 2002; Sleutels *et al*., 2003). A subtle variant of this theme is seen in the ube3A locus, in which there is brain-specific silencing of the paternal allele that appears to be dependent upon a brain-specific antisense ncRNA transcript (Landers *et al*., 2004). There are at least 70 known imprinted loci in the mouse genome, and probably many more (Nikaido *et al*., 2003), and most express well-validated, imprinted, noncoding RNA transcripts (Goldmit and Bergman, 2004; Peters and Beechey, 2004). Although the X-chromosome is the only chromosome showing global monoallelic inactivation, the same phenomenon occurs in many regions of autosomes. The best characterized examples include odorant and pheromone receptors, immunoglobulin and T-cell receptors and many other receptors on the surface of immunocompetent cells, and many inducible lymphokines and cytokines (Chess *et al*., 1994; Mostoslavsky *et al*., 1998; Singh *et al*., 2003a,b; Ensminger and Chess, 2004a,b; Gimelbrant *et al*., 2005). The phenomenon is not restricted to inducible genes, or sensors

in the nervous and immune systems. Widespread evidence of asymmetric DNA replication, a feature of the X-chromosome, on regions of the autosomes, suggests that random and/or regulated allelic inactivation is also widespread. Recently, Gimelbrant *et al*. (2005) used this criterion to identify many additional genes that show this feature, and highlighted the fact that the widely expressed p120 beta-catenin gene can be expressed monoallelically, or biallelically, in different cell types. One example of allelic inactivation and asymmetric replication that was studied in detail was the tlr4 locus, which encodes a molecule needed for the recognition of bacterial lipopolysaccharide by macrophages. In mice that carry a nonfunctional mutant allele caused by a point mutation of tlr4, 50% of macrophages express the mutant allele and, consequently, are unresponsive to LPS. However, in heterozygotes in which one tlr4 allele is completely ablated, all macrophages express the wild-type tlr4 (Pereira *et al*., 2003). This finding indicates that there is an allele-counting mechanism, as in X-chromosome inactivation, that ensures that only one allele is active. In all probability, this counting mechanism also involves ncRNA.

In view of these many examples of cis-acting effects of ncRNA, one cannot dismiss the transcripts derived from enhancers as noise. Such ncRNA might act to interrupt the chromosome-wide, or local, cis-acting effects of negative regulators. In the case of X-chromosome inactivation, the antisense gene *Tsix* determines X-chromosome choice and represses the noncoding silencer, *Xist.* In principle, Tsix action may involve RNA, the act of transcription, or local chromatin. Recent studies concluded that the processed antisense RNA does not act alone and that Tsix function specifically requires antiparallel transcription through *Xist* (Heard, 2004; Shibata and Lee, 2004). This example could provide a model for the actions of the many antisense transcripts that have been detected in large cDNA collections, and which may be derived from intronic or 3′ enhancer-like elements.

4.2. Trans-acting effects of ncRNA

With the rapid advances in RNAi technology, much of the focus on actions of ncRNA has been directed toward RNA interference. Many microRNAs are derived by processing of transcribed introns (Eddy, 2001), and there is an obvious possibility that many sense–antisense pairs identified in the mouse transcriptome (Kiyosawa *et al*., 2003) might function in a regulatory loop. A recent paper highlighted the identification of large numbers of intronic antisense transcripts in human cells, and correlated their levels with the state of differentiation of prostate cancer cells (Reis *et al*., 2004). The existence of large numbers of such transcripts has been confirmed in a global study of the human genome using tiling arrays (Bertone *et al*., 2004). It is not necessarily the case that such functional pairs will always show discordant regulation. In fact, in the expression analyses that we have performed in activated macrophages, sense and antisense pairs show no absolute trend toward concordant or discordant regulation, if anything more commonly showing concordance (unpublished). From a mechanistic viewpoint, antisense transcription could act to interfere with transcription initiation (directing transcriptional silencing), through transcription termination (it is not at all clear

what happens if transcription occurs on both strands simultaneously), RNA decay, or translational interference, but there is little direct evidence for any of these mechanisms in mammals as a major regulatory mechanism.

The other possible mechanism of action of ncRNA lies in their ability to bind to proteins. In the specific case of the small number of transcribed pseudogenes, they may act to regulate the translation or stability of the corresponding protein-coding transcript. At last one specific example has been documented (Hirotsune *et al*., 2003). The same mechanism might arise via the transcription of truncated noncoding transcripts. The noncoding imprinted H19 RNA associated with specific posttranscriptional stabilization of thioredoxin by an unknown mechanism (Lottin *et al*., 2002). RNA molecules can also bind in a sequence-specific manner to DNA-binding proteins. Members of the large C2H2 zinc finger transcription factor family, including the ubiquitous Sp1 transcription factor, bind with high affinity to DNA–RNA duplexes (Shi and Berg, 1995) and some transcription factors, such as Wt1, can also bind single-stranded RNA (Zhai *et al*., 2001). The capacity of RNA to bind to regulatory proteins including transcription factors in a sequence-specific manner provides many possible avenues for participation in regulatory networks.

Non-protein-coding RNAs clearly exist as reproducible transcriptional output of the genome. Views on the functions of ncRNAs range from the skeptical or dismissive, to the big picture perspective, which sees them as an essential component of a control network that is essential in the leap in complexity from prokaryotes to eukaryotes (Mattick, 2001). The latter view is theoretically attractive, but difficult to test experimentally. The addition of ncRNA to our view of the transcriptome provides a challenge to the perspective of the mammalian genome as being composed of genes and intergenic regions. To describe the set of transcripts encoded by the mouse genome, the FANTOM consortium adopted a definition of a transcriptional unit (TU) a cluster of transcripts with overlapping sequence bounded by the most extreme transcription start point and termination sequence. As more ncRNA are identified, these boundaries have extended, the number of TU has collapsed, and the number of TU with partial or complete antisense TU has increased. The boundaries of "genes" defy definition; we have found ourselves dealing with transcript forests separated by transcript deserts. A consequence of this pattern is that the numbers of ncRNAs that have actually already been knocked out in the mouse genome at least, and probably also in drosophila, is much greater than one might have recognized. Many knockout constructs or P-element insertions will have simultaneously ablated overlapping sense or antisense ncRNAs, which could contribute to a phenotype (or the lack of a phenotype) either by altering the function or expression of neighboring genes in cis, or other genes/alleles in trans. In the future, a detailed knowledge of the full transcriptional output of a locus will be an essential part of the interpretation of any functional genomic study in eukaryotes.

Short Specialist Review

The distribution of genes in human genome

Giorgio Bernardi
Laboratory of Molecular Evolution, Stazione Zoologica Anton Dohrn, Naples, Italy

1. Genome compartmentalization

Thirty years ago, we discovered that the bovine genome (neglecting satellite DNAs, which consist of tandemly repeated short sequences) was made of DNA molecules (about 30 kb in size in our work) of fairly uniform GC levels (GC is the molar percentage of guanine+cytosine in DNA). These DNA molecules belonged to a small number of families that covered a wide GC range (Filipski *et al*., 1973). Indeed, each family was comparable in compositional heterogeneity to prokaryotic genomes, the least heterogeneous genomes of living organisms. This was the first evidence that a mammalian genome was a mosaic of DNA segments belonging to different compositional families.

These initial observations were quickly extended to other vertebrates. The genomes of warm-blooded vertebrates essentially showed the compositional features just described for the bovine genome (Thiery *et al*., 1976). For example, in the human genome, five families of DNA molecules (neglecting satellite and ribosomal DNA) were identified and physically separated from each other. They were called L1, L2, H1, H2, and H3, in order of increasing GC level; the first three families comprised about 88% of DNA, the last two only about 12% (see Figure 1).

Further, investigations showed that the DNA molecules derived from much larger, fairly homogeneous DNA regions (at least 300 kb in size; Macaya *et al*., 1976), which were called *isochores* (for compositionally equal regions). The existence and the features of isochores were confirmed and visualized 25 years later (Pavliček *et al*., 2002) using the draft sequence of the human genome as soon as it became available (Lander *et al*., 2001; Venter *et al*., 2001; see Figure 2).

2. Genome phenotypes

In contrast to warm-blooded vertebrates, cold-blooded vertebrates showed a less striking heterogeneity, because their GC-richest isochores were not as GC-rich as in warm-blooded vertebrates (Figure 3). Most interestingly, the compositional patterns

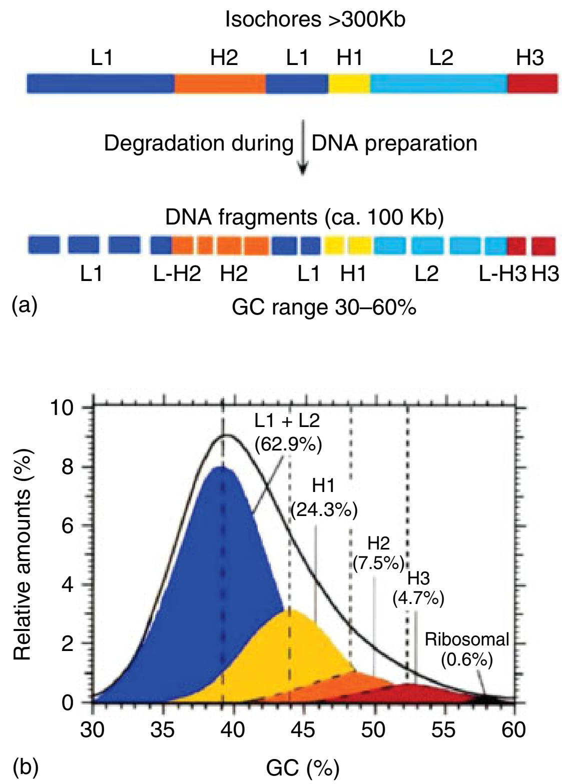

Figure 1 (a) Scheme of the isochore organization of the human genome. This genome, which is typical of the genome of most mammals, is a mosaic of large DNA segments, the isochores, which are compositionally fairly homogeneous and can be partitioned into a small number of families, light, or GC-poor (L1 and L2), and heavy, or GC-rich (H1, H2, and H3). Isochores are degraded during DNA preparation to fragments of 50–100 kb in size. The GC range of these DNA molecules from the human genome is extremely broad, 30 to 60%. (Reprinted with permission from the Annual Reviews of Genetics, Volume 29. Copyright 1995 by Annual Reviews **www.annualreviews.org**). (b) The CsCl profile of human DNA is resolved into its major DNA components, namely, DNA fragments derived from each one of the isochore families (L1, L2, H1, H2, and H3). Modal GC levels of isochore families are indicated on the abscissa (broken vertical lines). The relative amounts of major DNA components are indicated. Satellite DNAs (which form only a very few percent of the human genome) are not represented. (Reprinted from Zoubak *et al*., The gene distribution of the human genome, *Gene*, **174**, 95–102, Copyright 1996, with permission from Elsevier)

of the genomes of vertebrates are mimicked by the compositional patterns of coding sequences (that only represent 1–2% of the genomes in most vertebrates). Both compositional patterns amount to "genome phenotypes" (see Figure 3). This is a new concept compared to the "classical phenotype", which is represented by form and function, or, in molecular terms, by proteins and their expression.

It is important to note that an isochore organization of the genome is not limited to vertebrates, but is very widespread in eukaryotes, being also found in plants, insects, trypanosomes, and so on (see Bernardi, 2004).

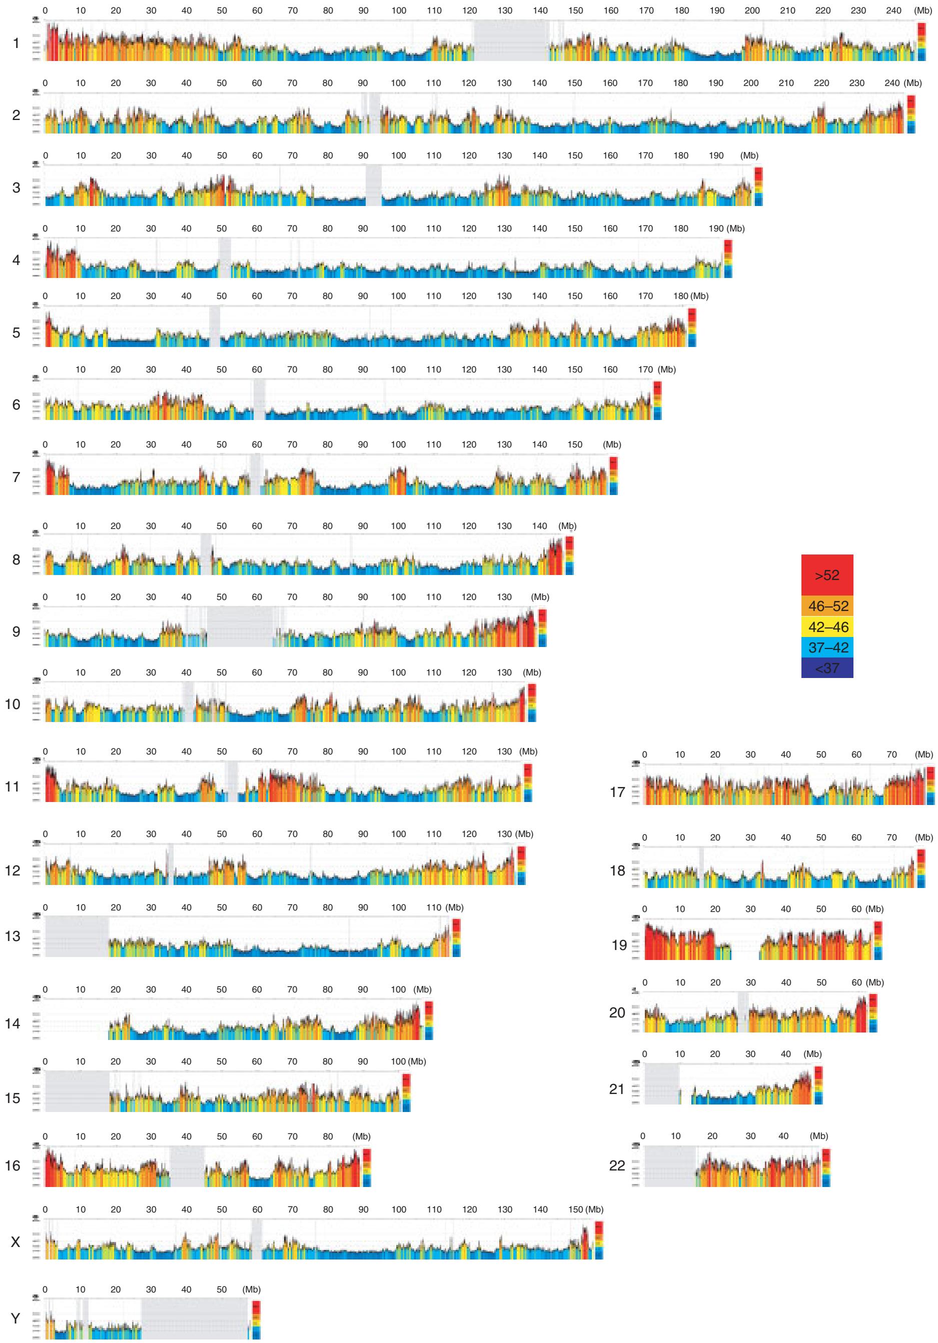

Figure 2 A color-coded compositional map of human chromosomes, representing 100 kb moving window plots that scan the human genome sequence. Color codes span the spectrum of GC levels in five steps, from ultramarine blue (GC-poorest isochores) to scarlet red (GC-richest isochores). Gray vertical lines correspond to the gaps present in the euchromatic part of the chromosomes. Gray bands to centromeres (Modified from Costantini *et al*., 2005)

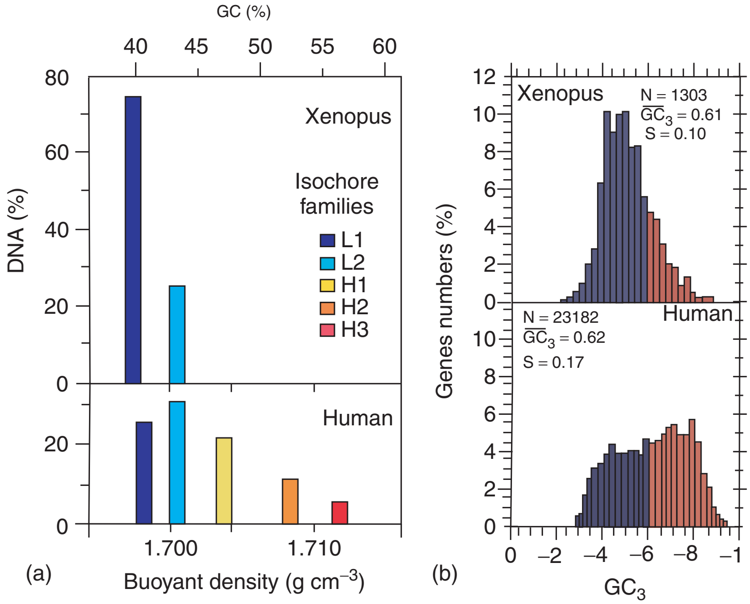

Figure 3 (a) Isochore families from *Xenopus* and human, as deduced from density gradient centrifugation. (b) Compositional patterns of coding sequences (represented by GC_3 values averaged per coding sequence; GC_3 is the GC level of third codon positions) for *Xenopus* and human. (Modified from Bernardi, 1995)

3. The genomic code

An obvious question is whether there is any correlation between the composition of coding and contiguous noncoding sequences. The answer is positive. Indeed, GC-rich coding sequences are flanked by GC-rich noncoding sequences, whereas GC-poor coding sequences are flanked by GC-poor noncoding sequences (Figure 4a). In fact, the *genomic code* (as these correlations were called) extends further, since compositional correlations also hold between exons and introns (Figure 4b) and among codon positions (see Figure 4c), the latter being valid from prokaryotes to mammals and being, therefore, called *universal correlations* (D'Onofrio and Bernardi, 1992). Finally, correlations also exist between the composition of coding sequences and the hydrophobicity and secondary structure (aperiodic, helix, strand) of the encoded proteins (Figure 5).

It should be stressed that the genomic code provided the first evidence for the eukaryotic genome being an *integrated ensemble*. One could also say that the genomic code has shown, to paraphrase Galileo, that the book of the genome is written in a mathematical language. Obviously, the genomic code cannot be reconciled with the idea of noncoding sequences being "junk DNA" (Ohno, 1972) and with the idea that "repeated sequences" like Alus and LINEs are "selfish DNAs" (Doolittle and Sapienza, 1980; Orgel and Crick, 1980). Indeed, if the base composition of coding sequences is under selection for thermal stability (see Bernardi,

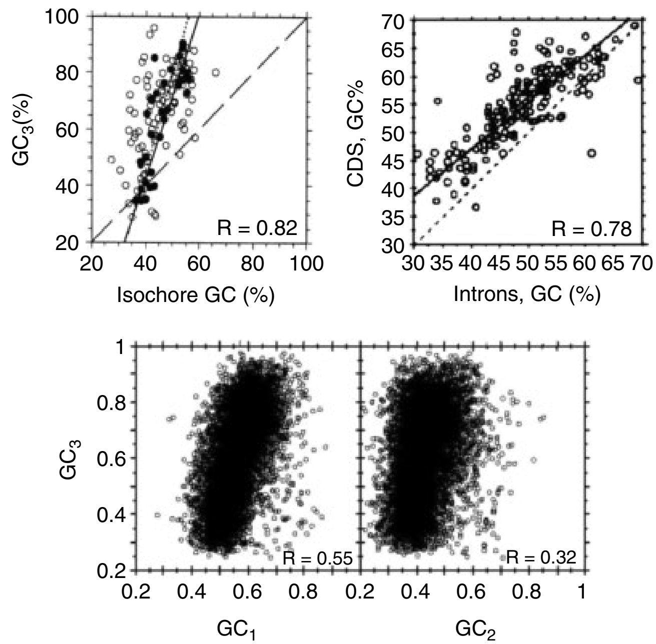

Figure 4 (a) Correlations between GC_3 of human genes and the GC level of DNA fractions or YACs (Yeast Artificial Chromosomes) in which the genes were localized (filled circles), or of 3′ flanking sequences (open circles; from Zoubak *et al*., 1996). (b) Correlations between GC levels of human coding sequences (CDS) and of the corresponding introns (Modified from Clay *et al*., 1996). (c) Correlations between GC_3 and GC_1 or GC_2 for 20 148 human genes (Modified from Jabbari *et al*., 2003)

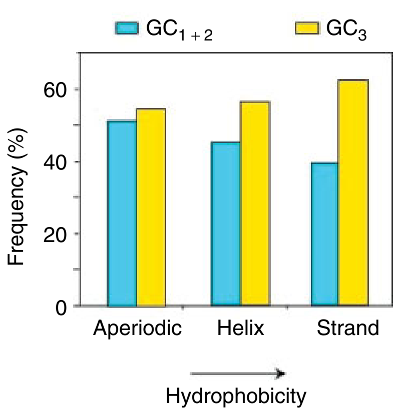

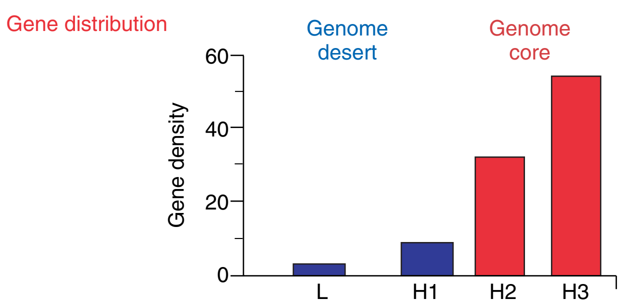

Figure 5 Histogram of the frequencies of GC_3 and GC_{1+2} in the three secondary structures of the proteins, which were ordered according to increasing hydrophobicity (Reprinted from D'Onofrio *et al*., 2002 The base composition of the genes is correlated with the secondary structures of the encoded proteins, *Gene,* **300**, 179–187, Copyright 2002, with permission from Elsevier)

2004), so must be noncoding sequences, since their composition is correlated with that of coding sequences.

4. Gene distribution in isochores and chromosomes

Two most important properties of vertebrates (as well as of other eukaryotes) concern the distribution of genes in the genome and in chromosomes and the correlations of such gene distributions with other structural and functional properties (Figure 6). The first indication that gene distribution was strikingly nonuniform (in contrast with the then current views) was published 20 years ago (Bernardi *et al*., 1985). Further work (Mouchiroud *et al*., 1991; Zoubak *et al*., 1996) identified two gene spaces, a *genome core* (the GC-rich isochore families H2 and H3) characterized by a high gene density and a *genome desert* (the GC-poor isochore families L1, L2, and H1), where gene density is low (see Figure 6). The genome desert and the genome core represent about 88% and 12%, respectively, of the genome, whereas the gene number is approximately the same in the two "gene spaces".

The two gene spaces are associated, as just mentioned, with different structural, functional, and evolutionary properties (see Figure 6). Among the former ones, the size of introns and untranslated regions (UTR) are large in the genome desert, but small in the genome core. The distribution of the DNA from the two gene spaces is quite different in metaphase chromosomes, the gene-dense regions of H2 and H3

Correlations with structure and function

Intro, UTR size	Large	Small
Chromatin structure	Closed	Open
GC Heterogeneity	Low	High
Gene experssion	Low	High
Replication timing	Late	Early
Recombination	Low	High

Figure 6 Gene distribution in the human genome. The major structural, functional, and evolutionary properties associated with each gene space are listed

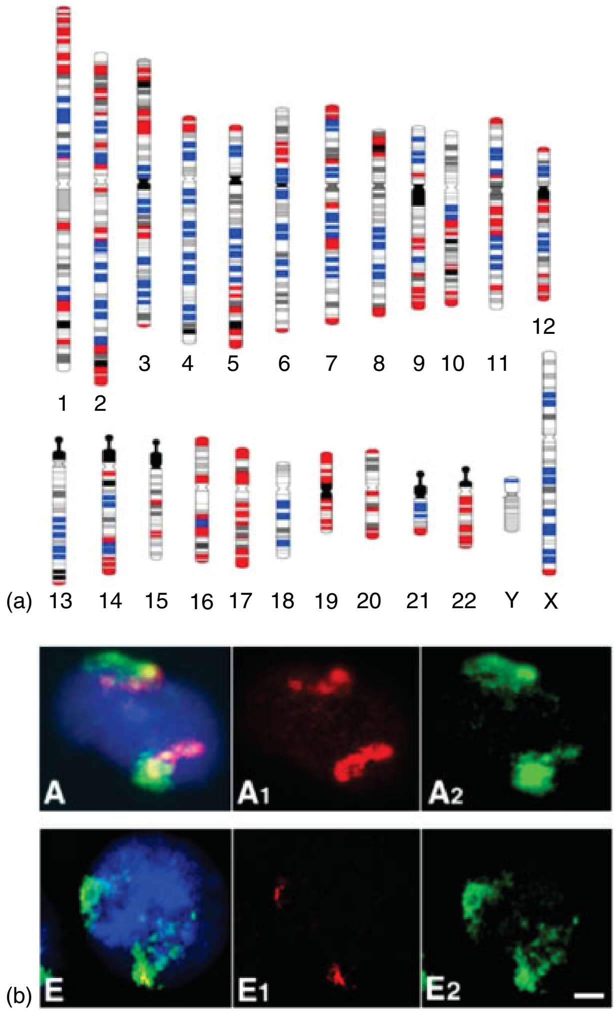

Figure 7 (a) Identification of the GC-poorest and the GC-richest chromosomal bands. Human karyotype at a resolution of 850 bands showing the chromosomal bands containing the GC-poorest (L1+, blue bars) and the GC-richest isochores (H3 +, red bars). The former correspond to G (iemsa) bands, the latter to R (everse) bands. The "intermediate" bands (the 50% of 80 bands that are neither GC- and gene-poorest nor GC- and gene-richest) are shown in white for the $H3^-$ R bands, in gray (according to Francke, 1994) for the $L1^-$ G bands (Modified from Federico *et al*., 2000). (b) Nuclear distribution of chromosomal regions characterized by different GC levels. 15–20 Mb chromosomal regions corresponding to GC-richest bands 6p21 (A) and 12q21 GC-poorest (E) were cohybridized with the corresponding chromosome probes. Band and chromosome DNAs were biotin- (red signals) and digoxigenin- (green signals) labeled, respectively. Nuclei were DAPI stained (blue). (Reprinted from Saccone *et al*., 2002 Localization of the gene-richest and the gene-poorest isochores in the interphase nuclei of mammals and birds. *Gene*, **300**, 169–178, Copyright 2002, with permission from Elsevier)

isochores being predominant in or near telomeres, the gene-poor regions mainly near the centromeres (Figure 7a). Most interestingly, in the interphase nucleus, the gene-dense regions of chromosome are very "open" and centrally located, whereas the gene-poor regions are densely packed against the nuclear membrane (Figure 7b).

This latter finding not only accounts for the fact that gene-dense regions have a high transcription level compared to gene-poor regions but also for the need of the open chromatin of the former to be stabilized thermodynamically by a GC increase at the emergence of warm-blooded vertebrates. In contrast, the gene-poor regions are stabilized by their closed chromatin structure. Other distinctive functional properties concern replication timing (late and early in the genome desert and in the genome core, respectively) and recombination, which is frequent in the first case and rare in the second.

In summary, the bimodal gene distribution revealed by the compositional approach used in our work and confirmed by all subsequent sequencing investigations (*see* Article 28, **The distribution of genes in human genome**, Volume 3) is strongly correlated with essential structural, functional, and evolutionary properties of the genome.

Short Specialist Review

Pseudogenes

David Torrents
European Molecular Biology Laboratory, Heidelberg, Germany

Pseudogenes are genomic regions that derive from genes but have no function (Balakirev and Ayala, 2003; Mighell *et al*., 2000; Vanin, 1985; Zhang and Gerstein, 2004). Because they have been traditionally assumed to present no biological relevance, the identification and classification of pseudogenes has attracted little attention and was initially restricted to evolutionary studies. Over the years, a significant number of pseudogenes have been accidentally uncovered during the analysis of gene-containing regions in different genomes, but their sequences and locations were rarely reported to public databases. It is in only recently that scientists became aware of the importance of identifying and annotating pseudogenes. Part of this growing attention derives from the need to provide basic annotation of recently sequenced genomes, which should include pseudogenes. But it is from the observation that a significant fraction of likely nonfunctional regions (pseudogenes) were being wrongly annotated as functional genes during preliminary analyses of completed large genomes (Gibbs *et al*., 2004; Lander *et al*., 2001; Waterston *et al*., 2002), that the identification and classification of pseudogenes has become extremely relevant. It is now required for any automatic approach for predicting genes to take into account the presence of pseudogenes and to include some rules to distinguish them. Finally, because of the increasing number of reports providing evidence that some regions previously classified as pseudogenes are actually functional, normally involved in the regulation of gene expression (Korneev *et al*., 1999; Healy *et al*., 1991; Hirotsune *et al*., 2003), collections of dead genes become an excellent source for the identification of additional examples of this type.

Although pseudogenes can exceptionally arise from the direct inactivation of functional genes, the vast majority of them are formed through gene duplication. In mammals, two major mechanisms of gene duplication coexist, with different impact on pseudogene formation and gene evolution: (1) The s*egmental duplication* of genes results in the formation of identical copies, mostly through unequal crossing-over during meiotic recombination (Alberts *et al*., 1994). This type of duplication might also involve the copy of the promoter and other regulatory regions along with the coding region. Therefore, favored by an initial period of functional redundancy and relaxed selective constraint, expressed duplicates might undergo sequence modifications that lead to the acquisition of new, or more specialized functions. Although the ultimate fate of most segmental duplicated genes

is unclear in terms of their preservation and the acquisition of new functions, it is commonly accepted that, one of the copies usually becomes a *nonprocessed pseudogene* through the accumulation of lethal mutations, whereas the other retains the original (or eventually enhanced) function (Force *et al*., 1999; Ohno, 1970; Lynch and Conery, 2000). Alternatively segmental duplications might only involve fragments of genes that will likely result in the formation of incomplete and hence nonfunctional gene copies. (2) A second mechanism of gene duplication corresponds to *retrotransposition*, which generates *processed* gene copies. This duplication mechanism results in the copy of mature RNAs, through their retrotranscription and integration back into the genome, using the machinery of retrotransposable elements (Esnault *et al*., 2000). In contrast to some segmental gene duplicates, processed mRNA copies carry no signals for transcription initiation. Because mRNA copies insert randomly in the genome, that is, likely far from active promoters, retrotransposed gene copies are rarely ever expressed and can therefore be considered "dead on arrival". However, there are isolated examples of functional genes that have arisen through the retrotransposition of mRNAs (Lander *et al*., 2001; Brosius, 1999; Burki and Kaessmann, 2004). The absence of introns and the presence of flanking repeats and polyA tail are clear characteristics that can be used (when detectable) to distinguish retrotransposed gene copies from segmental duplicated copies.

But how are pseudogenes recognized? Following the general definition, a given genomic region can be cataloged as pseudogenic when it shows homology to an active gene and has no function. Whereas homology is relatively easy to identify through the detection of significant sequence similarity, the absence of function remains impossible to prove, given all possible (new and subtle) types of biological roles in which a particular region can be involved. Nevertheless, a few characteristics that have been found in a number of gene duplicates have been accepted as strong indicators for the absence of functionality. These features have been used to report, not only single cases, but also large collections of pseudogenes from different organisms.

The first reports describing pseudogenes relied on the absence of transcription to propose the absence of functionality. In fact, the term *pseudogene* was first introduced in 1977 to describe a tandem copy of the *Xenopus laevis* 5 S RNA gene for which evidence of expression could not be initially found (Jacq *et al*., 1977). The same region was later shown to be actually expressed but with "inefficient termination" of transcription (Miller and Melton, 1981). Soon after, structurally identical copies of the rabbit and human globin genes were identified next to their functional paralogs and classified as pseudogenes, using again questionable arguments to propose nonfunctionality (Fritsch *et al*., 1980; Hardison *et al*., 1979; Lauer *et al*., 1980). Because the impossibility to detect expression of segmental duplicated genes can derive from methodological limitations, this argument is nowadays considered insufficient to suggest nonfunctionality. Even the classification of retrotransposed gene copies as nonfunctional or pseudogenic requires additional evidence, even though they are unlikely to ever be transcribed.

The detection of truncations, that is, in-frame stop codons or frameshifts, within duplicated protein coding regions is accepted as the most convincing evidence to disprove functionality, as their presence is generally not compatible with

the synthesis of complete and operative proteins. Through systematic searches of truncated and nearly complete retrotransposed gene copies, two independent approaches identified in human genome, 3500 (Ohshima *et al*., 2003) and 8000 (Zhang *et al*., 2003) processed pseudogenes. Similar procedures detected processed pseudogenes in other genomes, including puffer fish (Dasilva *et al*., 2002), fruit fly (Harrison *et al*., 2003), worm (Harrison *et al*., 2001), and yeast (Harrison *et al*., 2002). But these approaches, despite presenting a high specificity, overlooked an important fraction of pseudogenes, which include those with an apparently intact coding region, but with other type of lethal mutations (e.g., replacements of functionally essential amino acids, or disrupted or missing promoters), pseudogenes arising from segmental duplications, and all pseudogenes with incomplete coding regions.

At the same time, another study used a different principle to evaluate the presence or absence of functionality for detectable gene copies in human (Torrents *et al*., 2003), which did not depend either on the presence of truncations or on the mechanism of duplication, that is, it covered both retrotransposed and segmental duplicated pseudogenes. 20 000 complete and partial gene copies identified between predicted and known functional genes were evaluated as to functionality, only taking into account the ratio of silent (synonymous, K_S) to amino acid replacement (nonsynonymous, K_A) substitutions, which indicates the associated levels of selective constraint (Li *et al*., 1981). K_A/K_S ratios of pseudogenes and those of the vast majority of genes are generally different, as mutations in genes causing amino acid replacements with functional consequences are selected against, in contrast to mutations occurring in pseudogenes. This functionality test revealed that nearly all identified gene copies were neutrally evolving and therefore nonfunctional. The regions identified with this approach, despite constituting the largest set of nonfunctional gene copies identified so far, were estimated to correspond to a fraction of the complete population of human pseudogenes, which is likely to exceed the number of genes. Following the same detection and classification strategy, a similar number of pseudogenes were identified in mouse and rat (Gibbs *et al*., 2004). From the comparative analysis of human and mouse orthologous DNA blocks, the same study showed that the majority (>70%) of the pseudogenes are located far from their functional paralogs, which is consistent with a retrotranspositional origin. This distinction also revealed that although the number of both processed and nonprocessed pseudogenes correlates with the size of the chromosomes in human, their intrachromosomal distribution differs: processed pseudogenes are more abundant close to telomeres, nonprocessed pseudogenes are normally enriched in gene dense regions.

All mammalian genomes investigated so far appear to have a high and similar number of detectable pseudogenes (~20 000), suggesting that they share similar mechanisms (and rates) for the formation and death of this type of regions (Gibbs *et al*., 2004; Torrents *et al*., 2003). On the other hand, other vertebrates, such as chicken, appears to heave nearly an undetectable number of processed pseudogenes (ICGSC, 2004), which is likely due to the lack of interaction between the machinery of active retrotransposons with host mRNAs. Similarly, a number of searches within nonvertebrate genomes revealed in general a low number of both processed and nonprocessed pseudogenes (Harrison *et al*., 2003; Harrison *et al*., 2001; Harrison

et al., 2002; Zdobnov *et al*., 2002), which could be in agreement with the observed size constraints associated to their genomes (Petrov and Hartl, 2000).

Between the years 2001 and 2003, important progress has been achieved in the identification and classification of pseudogenes. Nevertheless, we expect that the sequencing of more genomes, and particularly the increasing availability of new experimental data revealing atypical forms of functionality, will provide, in a close future, additional criteria for the difficult task of distinguishing between functional and pseudogenic gene duplicates. This will then allow significant improvements to be made in the construction of pseudogene catalogs and to investigate their actual impact on gene and genome evolution.

Short Specialist Review

Alternative splicing: conservation and function

Mikhail S. Gelfand
Institute for Information Transmission Problems, Moscow, Russia

Evgenia V. Kriventseva
BASF Plant Science GmbH, Ludwigshafen, Germany

At least half of human genes seem to be alternatively spliced (Lander *et al.*, 2001). This estimate is mainly based on the comparison of genomic DNA with EST (expressed sequence tag, *see* Article 78, **What is an EST?**, Volume 4) sequences (Mironov *et al.*, 1999; Brett *et al.*, 2000), and thus is subject to uncertainty stemming from the fact that the ESTs do not necessarily correspond to functional mRNA. Even if experimental artifacts such as underspliced transcripts could be eliminated, there remains a problem of errors by the splicing machinery itself, the so-called aberrant splicing (*see* Article 87, **Manufacturing EST libraries**, Volume 4).

Indeed, the normalization of mRNA concentrations during construction of clone libraries leads to the sequencing of ESTs arising from rare mRNA isoforms. Further, computational analysis has demonstrated the existence of numerous cancer-specific ESTs (more exactly, ESTs corresponding to cancer-specific alternatively spliced isoforms, *see* Article 82, **Using ORESTES ESTs to mine gene cancer expression data**, Volume 4) (Wang *et al.*, 2003; Sorek *et al.*, 2003; Xie *et al.*, 2002; Xu and Lee, 2003), the emergence of which could be due to the general disruption of control mechanisms in cancerous cell lines. Although one could claim that almost all human genes show some evidence of alternative splicing, when stricter criteria are considered (e.g. at least two ESTs supporting an alternative splicing event), the fraction of alternatively spliced genes decreases to 17–28% (Kan *et al.*, 2002).

A new twist to this discussion was added when several groups attempted to compare alternative splicing of human and mouse genes (Thanaraj *et al.*, 2003; Modrek and Lee, 2003; Modrek *et al.*, 2001; Nurtdinov *et al.*, 2003). Surprisingly, it turned out that a considerable fraction of human genes have alternatively spliced isoforms, which are not conserved in mouse.

Two different approaches have been applied to compare human and mouse alternative splicing. One of them was a direct comparison of human and mouse ESTs. This approach demonstrated that at least 15% of human splice junctions (introns) are conserved in mouse (Thanaraj *et al.*, 2003). A similar estimate was

made for different types of elementary alternatives considered separately, at that, exon skipping events were shown to be more conserved than alternative splicing sites (Sugnet *et al*., 2004). However, as the mouse EST data at least is far from saturation, this is clearly a lower bound on the fraction of conserved alternative splicing.

The other approach is based on aligning human protein isoforms to mouse genomic DNA using spliced alignment algorithms (Mironov *et al*., 2001; *see also* Article 15, **Spliced alignment**, Volume 7) or simply BLAST (Altschul *et al*., 1997; *see also* Article 39, **IMPALA/RPS-BLAST/PSI-BLAST in protein sequence analysis**, Volume 7). At that, an isoform is assumed to be conserved if the alternative region aligns to the mouse genome without frameshifts and is bounded by the standard GT-AG dinucleotides. It is clear that this definition yields an upper estimate on the number of conserved isoforms, since these conditions are necessary but not sufficient: an isoform may be nonexistent due to changes in splicing site positions other than GT-AG, or to changes in regulatory sites such as splicing enhancers. Further, this definition does not take into account nonconserved exon skipping events.

This approach, applied in (Nurtdinov *et al*., 2003), demonstrated that at least half (55%) of 166 alternatively spliced human genes had isoforms not conserved in their mouse orthologs. This was due to about 25% of unconserved elementary alternatives. Notably, similar results were obtained for elementary alternatives confirmed by mRNAs (24% nonconserved) and by ESTs only (31%).

A much larger sample in a similar setting was analyzed in (Modrek and Lee, 2003), where only cassette exons were considered. All such exons were divided into exons included in the major isoforms (i.e., present in the majority of ESTs overlapping the relevant region) and the minor form exons. The former were found to be conserved in 98% of cases, whereas only about a quarter (27%) of the latter were conserved. Similar results were obtained in a smaller-scale human–rat comparison. The average conservation of both types of exons, 75%, is remarkably close to the degree of conservation of elementary alternatives reported in (Nurtdinov *et al*., 2003).

An important question is whether these nonconserved alternatives are real or arise from splicing errors, and so on. The number of documented functional nonconserved alternatively spliced isoforms is not large (Nurtdinov *et al*., 2003). In fact, it has been suggested that most nonconserved isoforms are not functional (Sorek *et al*., 2004). The fraction of nonconserved cassette (skipped) exons, identified by a combination of EST analysis and genomic comparisons, was similar to that of the two studies mentioned above (75%). However, it was demonstrated that most nonconserved exons (79%) either led to a frameshift (because their length did not contain an integer number of triplets) or contained an in-frame stop codon. By contrast, only 27% of conserved cassette exons interrupted the reading frame. The difference decreased when exons supported by multiple ESTs were considered (46% interrupting exons, among exons supported by at least five ESTs).

Does that mean that the majority of nonconserved isoforms are nonfunctional? Frame interruption per se does not make an isoform nonfunctional. Indeed, about 40% of both human (Modrek *et al*., 2001) and mouse (Zavolan *et al*., 2002) alternative isoforms identified from EST and full-length cDNA analysis have an

interrupted reading frame, and a slightly smaller estimate (22%) was obtained in the analysis of published experimental data (Thanaraj and Stamm, 2003). An intermediate number of alternative isoforms (35%) was reported in (Lewis *et al*., 2003); moreover, it was demonstrated that most such isoforms would be subject to nonsense-mediated mRNA decay, as the stop codon occurred more than fifty nucleotide upstream of the 5′-most exon–exon junction. As this trend persisted after the filtering of less-reliable isoforms, it is likely that the frame-interrupting isoforms are functional; one suggested possibility was that they are involved in the regulation of splicing, translation, and mRNA degradation.

Indeed, a different line of evidence for functionality of nonconserved isoforms was considered in (Modrek and Lee, 2003). In many cases, the minor form nonconserved exons not only were supported by multiple ESTs but also demonstrated evidence for tissue-specific expression, and constituted a majority in this tissue.

Thus, an open question seems to be not the reality of nonconserved isoforms but their functionality. A large-scale proteomic study will be necessary to determine whether these isoforms are translated and yielded protein products.

In any case, alternative splicing was demonstrated to have a major effect on the protein structure (Kriventseva *et al*., 2003). Indeed, when compared with a random model, alternative splicing was shown to prefer shuffling complete protein domains instead of disrupting domains or falling into interdomain regions and to target functional sites when it is occurring within a domain. Indeed, alternative splicing often involves domains implicated in protein–protein interactions (Resch *et al*., 2004). Further, it was shown that alternative splicing has a tendency to remove gene regions encoding signal peptides and single transmembrane segments, thus producing secreted, membrane-bound, and cytozolic isoforms of proteins (Xing *et al*., 2003; Cline *et al*., 2004).

Thus, alternative splicing is a major mechanism for generating protein diversity, both in extant organisms and in evolution. The latter explanation is supported by additional observations: evidence for positive selection based on analysis of synonymous and nonsynonymous nucleotide substitutions (Iida and Akashi, 2000) and the fact that all Alu-derived protein-coding regions of human genes are alternatively spliced (Sorek *et al*., 2004). Indeed, an elegant theory of Modrek and Lee (2003) states that alternative splicing provides an organism with a possibility to experiment with new protein functions while not disrupting the old protein. If a new variant proves to be beneficial, its fraction may increase due to subtle changes in regulatory sites.

However, this does not explain why generation of protein variability cannot be obtained by gene duplication. Another less-appreciated role of alternative splicing could be that of maintaining *protein identity*. Indeed, in many cases, a cell needs proteins that are different in some domains and exactly identical in others. The most obvious example of this is given by membrane, secreted, and intracellular isoforms of various receptors. The recognition or ligand-binding domain should be the same, whereas the membrane anchor or a signal peptide is encoded by alternative exons. It is clear that such an arrangement cannot be obtained by gene duplication, as this would require an expensive mechanism for maintaining the identity of those DNA fragments that should encode identical domains.

Overall, computational comparative analysis of alternative splicing is a hot and important topic. The next step probably would be in merging the diverse approaches, aimed at the description of all aspects of the alternative splicing phenomenon: evolution of the exon–intron structure and of sequence in alternatively spliced regions, regulation, consequences for the protein structure and function, and so on. And, it is clear that such analyses will not be restricted to the study of mammals (human–mouse–rat). Other appealing groups of already available genomes are the two nematodes (*Caenorhabditis elegans* and *Caenorhabditis briggsae*, *see* Article 44, **The *C. elegans* genome**, Volume 3) and also fruit flies (*Drosophila melanogaster*, *Drosophila pseudoobscura*, and others) with the malarial mosquito *Anopheles gambiae* serving as an outlier; to be complemented, as sequencing of eukaryotic genomes progresses, by chicken, fishes (*Takifugu rubrupes*, *Danio rerio*, *see* Article 46, **The Fugu and Zebrafish genomes**, Volume 3), honeybee, and plants.

Short Specialist Review

Overlapping genes in the human genome

Izabela Makalowska
Pennsylvania State University, University Park, PA, USA

Viruses have very compact genomes. Yet, the discovery of the overlapping genes in bacteriophage phiX174 in1976 (Barrell *et al*., 1976) came as a surprise. It took another decade before similar phenomena were noticed in higher eukaryotes. In 1998, in the same issue of Nature, Spencer *et al*. (Spencer *et al*., 1986) published two overlapping genes in Drosophila and Williams and Fried (1986) reported the same pattern in mouse. However, overlapping genes in mammalian genomes are unexpected phenomena. Why, one can ask, despite vast genome-less genomic area do some genes overlap in mammalian genome? Regardless of numerous reports about overlapping genes in human, until recently, overlapping genes were not considered to be important or a large-scale event in human and other vertebrates' genomes. The only exceptions were genes within genes, which relatively early were believed to be a common feature of nuclear genomes. Large-scale EST and genomic sequence studies led to the conclusion that overlapping genes, other than genes embedded in another gene intron, are commonly present in higher eukaryotes.

Overlapping genes may be divided into several types. The major division would depend on the genes' direction, and we can observe overlapping genes on the same strand and on opposite strands. The latter category, an antitranscript overlapping gene, is our main focus. Among these, we can observe genes that share the same locus but the overlaps are only between exonic region in one gene and intronic area in another and genes that share not only locus but also exonic sequences. Depending on which parts of two genes share the genomic region, we can also categorize these overlaps as head to head, when the overlap is in the 5′ region of both genes, or tail to tail when the overlap involves 3′ regions. Special types already mentioned are embedded genes, a case in which one gene lies completely in the area of another one. Sometimes we can observe that several genes are embedded in the genomic locus of a gene on the opposite strand. For example, intron 27 of human neurofibromatosis type 1 gene (NF1) contains three other genes: *OMG*, *EVI2B*, and *EVI2A*. Examples of different categories of overlapping genes are shown in Figure 1.

The total number of overlapping genes in human and other nuclear genomes is still unknown. So far, reported numbers vary from 774 pairs (Veeramachaneni *et al*., 2004) to well above 2000 (Yelin *et al*., 2003). The discrepancy is mostly

caused by different type of data used and both numbers may actually be correct. In the first studies, only protein coding cDNAs were analyzed and in the second one, all human ESTs including nonprotein coding genes were considered. From the studies of mouse overlapping genes (Kiyosawa *et al*., 2003), we know that about 75% of genes overlap involve at least one noncoding gene. However, we may expect the number of overlapping genes in human genome to be higher and a good fraction of them have not yet been discovered owing to incomplete sequence data.

The biologic functions of natural antisense transcripts, their involvement in physiological processes, and gene regulation in living organisms are barely known. There is speculation that they form a double-stranded RNA to downregulate the expression of sense RNA molecules. However, so far, large-scale analysis has not shown any significant correlation in terms of function, localization, or process between two members of sense–antisense pairs and the distribution of overlapping genes regarding these parameters was found to be not significantly different from the rest of human genes (Yelin *et al*., 2003). Forming a double-stranded RNA to downregulate the expression of an RNA molecule may be a good explanation for some fraction of overlapping genes, especially when noncoding RNA is involved. But in protein coding genes, it would make the overlap quite hazardous since it could lead to RNA degradation and in extreme cases formation of antiparallel heteroduplex RNA could completely block the expression of both genes. Escape from such evolutionary pressure could be in differential expression and there are multiple examples of overlapping, protein coding genes showing clearly different temporospatial expression. However, there are also instances of overlapping genes being expressed at the same time and place. Therefore, regulation of expression of overlapping genes either does not always involve a counterpart gene or there are different mechanisms for doing this, not just by forming double-stranded RNA.

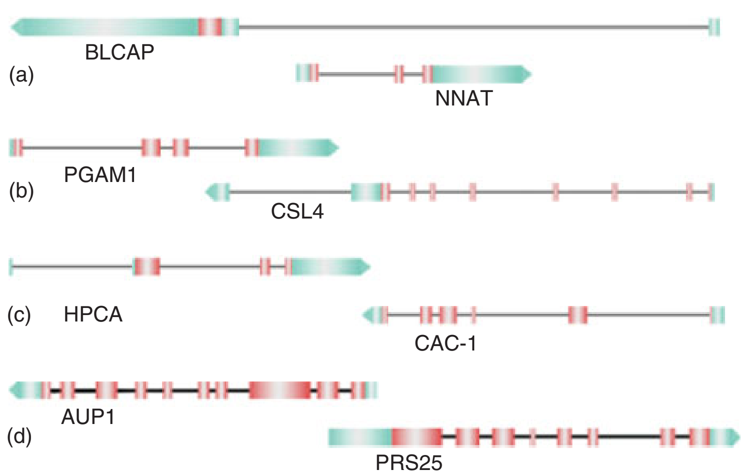

Figure 1 Examples of human overlapping genes. Red color indicates coding sequence and green color shows untranslated regions. (a) Imbedded gene, (b) genes sharing genomic regions with overlap between exon of one gene and intron of another, (c) tail-to-tail exons overlap, (d) head-to-head exons overlap. Red color denotes coding sequences and green color indicates untranslated regions

The evolution of overlapping genes is also unknown. We do not understand either the mechanism or the meaning of the origination of overlapping genes in higher eukaryotes. Keese and Gibbs (1992) suggested that overlapping genes arise as a result of overprinting – a process of generating new genes from preexisting nucleotide sequences. This process took place after the divergence of mammals from birds, and overlapping genes represent young, phylogenetically restricted genes encoding proteins with diverse functions, and are therefore specialized to the present lifestyle of the organism in which they are found.

Shintani *et al*. (1999) suggested that the overlap between the two genes studied by them, *ACAT2* and *TCP1*, arose during the transition from therapsid reptiles to mammals, and that the overlap could have happened in one of two ways. In one scenario, the rearrangement may have been accompanied by the loss of a part of the 3′-untranslated region, including the polyadenylation signal, from one gene. By chance, however, the 3′-UTR of the new neighbor on the opposite strand contained all the signals necessary for termination and transcription so that the translocated gene could continue to function. Alternatively, the two genes could have become neighbors through the rearrangement but did not overlap at first. Later, one of the genes lost its original polyadenylation signal, but was able to use a signal that happened to be present on the noncoding strand of the other gene. None of these hypotheses fully explains the nature of overlapping genes evolution. There is evidence that some human overlapping genes do not have othologs in other genomes (Makalowska *et al*., 2005), which support the hypothesis suggested by Keese and Geebs. On the other hand, there are many instances where genes overlap in one organism but are located next to each other, without any overlap, in another species.

Studies of overlapping *MINK* and *CHRNE* genes (Dan *et al*., 2002) provide some support for second hypothesis; however, it will only work well with genes overlapping at 3′ end. Results of this study show that mutations in the polyadenylation signal of the *CHRNE* gene resulted in the adoption of alternative signal conserved in the 3′-UTR of the *MINK* gene located downstream on the opposite strand. As an outcome, we observe an overlap between the last exons of these two genes. Analysis of genomes of different orders of placental mammals demonstrated that the CHRNA/MINK overlap occurred at least three times independently during the course of mammalian evolution, and all happened in distinct ways. One of these events most likely happened after the cercopithecoid/hominoid split. This means that many overlaps could be relatively young and the pattern of relation between genes does not have to be conserved among mammals. Confirmation of this may come from large-scale studies of human and mouse overlapping genes done by Veeramachaneni *et al*. (2004). Out of 255 human overlapping gene pairs, only in 95 cases were genes that were also overlapping in mouse and in 150 cases, genes were overlapping in human but not in mouse although both the genes were mapped next to each other.

It was expected that genes that overlap should be more conserved among species. Lipman (1997) explained the higher conservation of noncoding sequences of some genes exactly by the presence of antisense transcripts and therefore higher level of evolutionary pressure. However, genes that overlap in both human and mouse do not show statistically significant difference in the level of conservancy than

nonoverlapping genes (Veeramachaneni *et al*., 2004). The relation between overlap and level of conservation was also not observed by Dan *et al*. (2002). 3′-UTR of *MINK* gene was extremely conserved in all species, not in only those where the overlap occurred, and the 3′-UTR of *CHRNE* had overall faster evolutionary pace.

In conclusion, we can say that overlapping genes brought a new light and many questions into molecular evolution, genome structure, and gene functions. Despite many studies, the total number of such genes in higher eukaryotes, mechanism of their origination and functional significance are still awaiting full explanation.

Short Specialist Review

Comparisons with primate genomes

Mariano Rocchi and Nicoletta Archidiacono
University of Bari, Bari, Italy

The complete sequence of human, mouse, and rat genomes is now available, and sequence comparison has started to unveil the forces that shaped mammalian genomes. Whole-genome comparison among these three genomes is very interesting, but almost fruitless if used to delineate the recent evolutionary history of the human genome. Comparison of our genome with those of our closest relatives, the primates, is, with no doubt, much more rewarding in this respect. Unfortunately, only the chimpanzee genome, at draft level, is available.

Other approaches, however, have been exploited to unveil aspects of our recent evolution. Cytogenetics offers the opportunity of looking at genomes through variations of the pieces in which genomes are organized, the chromosomes. Cytogenetics came of age in the sixties when some technical achievements made it possible to culture peripheral human lymphocytes and prepare a large number of good-quality metaphases. Chromosomal count became an easy task and chromosomal syndromes as well as karyotype number of some primate species could be determined. It was noted, for instance, that the chimpanzee had 48 chromosomes, two more than man. The banding techniques era in seventies introduced a more powerful analytical tool in chromosome identification, and De Grouchy first suggested that the chromosomal number difference between humans and chimpanzee was due to the fact that two ancestral chromosomes, conserved in chimpanzee, fused to generate the human chromosome 2.

Dutrillaux did an extensive use of banding techniques in an attempt at a comprehensive view of karyotype evolution in primates, which are divided into prosimians, Platyrrhini (New World Monkeys, NWM), and Catarrhini (Old World Monkey and apes). Apes include lesser apes (gibbons) and great apes (orangutan, gorilla, chimpanzee). Yunis and Prakash (1982) reported a detailed analysis of chromosome similarities among great apes. This paper, which appeared in *Science*, defined all the changes detectable at high-resolution banding level. Figure 1 shows a comparative karyotype of human and great apes (chimpanzee, gorilla, and orangutan).

Heterochromatic blocks of rapidly evolving satellite DNA can differentiate even close species. For instance, heterochromatic DNA blocks are associated only with the centromeric domains of autosomes in humans, while in great apes, they are also telomerically and interstitially located (Figure 2). In addition, differences other

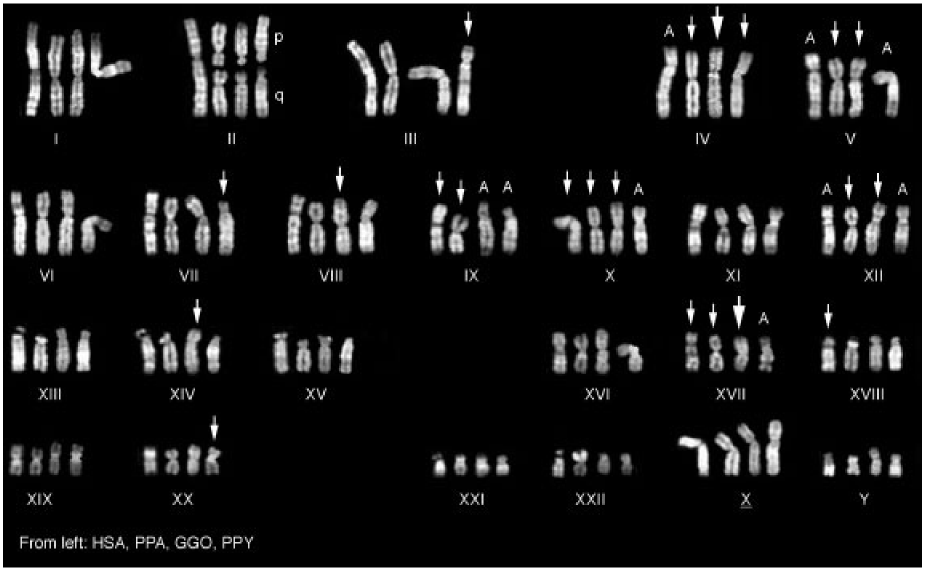

Figure 1 Comparative karyotype of human and great apes (pigmy chimpanzee, *Pan paniscus*, PPA; gorilla, *Gorilla gorilla*, GGO; Borneo orangutan, *Pongo pygmaeus pygmaeus*, PPY). Pigmy chimpanzee (bonobo) is one of the two chimpanzee species. The other one is the common chimpanzee (*Pan troglodytes*, PTR). They have an almost identical karyotype. The QM banded chromosomes are numbered according to the phylogenetic nomenclature (Roman numbers), which was introduced to better show the correspondence to human chromosomes, which is not evident using the specific chromosome number that is given according to the size of the chromosome. Note the chromosome 2 that resulted from the fusion of two ancestral acrocentric chromosomes. "A" stands for ancestral form; arrows point to derivative chromosomes, which usually differ from the ancestral form by an inversion. The ancestral form is not indicated when the chromosomes are identical. Minor changes were not considered. Gorilla shows the only translocation present in great apes (big arrow), involving chromosomes V and XVII. Some differences are only due to large heterochromatic blocks present in great apes (see Figure 2)

than rearrangements or heterochromatic blocks can strongly affect the structure of chromosomes. It has been recently shown, in this respect, that repeat-expansion in humans can account for up to 20% of DNA content difference between lemur and humans (Liu *et al*., 2003). Banding patterns analysis, therefore, could be misleading, especially when the species under study are not closely related.

The Fluorescence In Situ Hybridization (FISH) techniques introduced a completely new tool in cytogenetic investigations, and, being based on sequence homology, solved many of the problems posed by chromosomal similarities just based on visual inspection. These studies were pioneered by the J. Wienberg group and the T. Cremer (Jauch *et al*., 1992) groups in Germany. Figure 3 is an example of a cohybridization experiment using human painting probes on a gibbon metaphase. This single experiment discloses that gibbon chromosomes are very rearranged with respect to humans. The use of whole-chromosome paints and partial-chromosome paints, indeed, has the advantage of producing rapid results, but lacks resolution, and marker order remains frequently undetermined.

The human genome sequence generated by the public Consortium was achieved using a "hierarchical" approach. A minimal collection of overlapping clones,

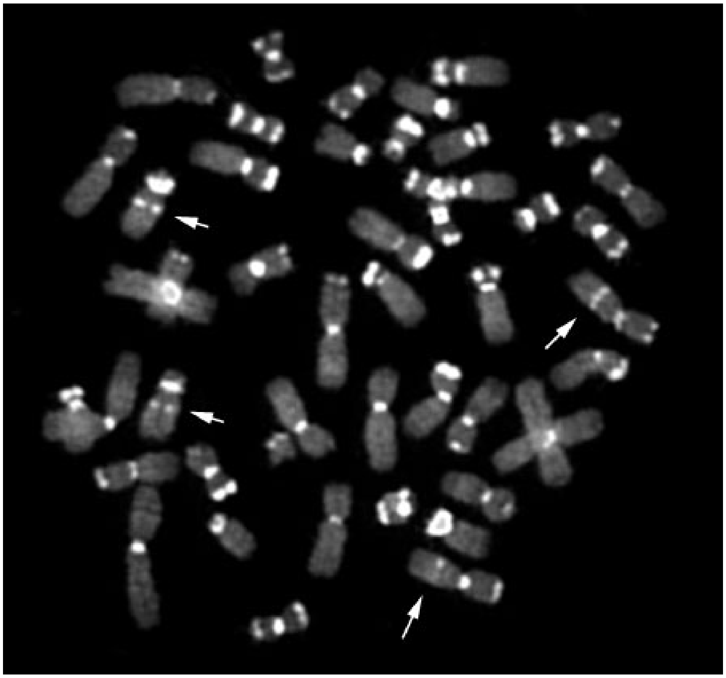

Figure 2 Metaphase form common chimpanzee (*Pan troglodytes*, PTR), showing heterochromatic blocks located on centromeres, telomeres, and in interstitial loci of chromosomes VII (arrow) and XIII (short arrow). The chromosomes are DAPI stained after the denaturation and hybridization procedure used for FISH (Fluorescence In Situ Hybridization)

covering the entire genome, was sequenced. As an intermediate step toward the definition of this "golden path", thousands of BAC/PAC clones were fingerprinted and end-sequenced. As a result, even if a specific clone was not chosen for complete sequencing, its position on the human sequence is defined at single base-pair resolution. In conclusion, for each region of the human genome, several overlapping probes are available and can be obtained from various sources, from the Pieter de Jong laboratory (Oackland) in particular, where most of the BAC/PAC probes were generated. The University California Santa Cruz browser (**http://genome.ucsc.edu**) specifically shows this large collection of end-sequenced clones. These resources are invaluable for molecular cytogenetics because they produce a clean and locus-specific signal in FISH experiments.

These resources have been used extensively to study marker order conservation in primates and led to the discovery of an unprecedented biological phenomenon: the evolutionary centromere repositioning. That is, the movement of the centromere along the chromosome not accompanied by any chromosomal rearrangement that would account for its movement. The first evolutionary centromere repositioning example was documented on chromosome 9 (Montefalcone *et al*., 1999). At present, several other examples have been reported (Ventura *et al*., 2001; Eder *et al*., 2003). The phenomenon appears to not be limited to primates (Band *et al*., 2000).

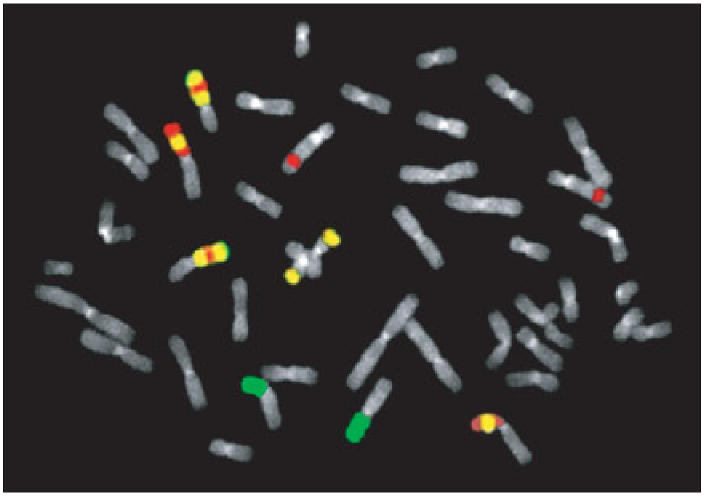

Figure 3 FISH experiment on a lar gibbon (*Hylobates lar,* HLA) metaphase using whole-chromosome paint specific for chromosome 3 (red) and a partial-chromosome paint specific for the short arm of this chromosome (3p) and for the short arm of chromosome X (green). 3p is part of the entire chromosome. 3p chromosomal segments of HLA are stained with red and green and, therefore, they appear yellow in the merged image. Portion of 3q are just red and Xp remain green. The experiment shows that HLA sequences corresponding to the human chromosome 3 are scattered in four different chromosomes but organized in at least eight distinct syntenic blocks

A centromere repositioning implies the inactivation of an ancestral centromere and the seeding of a neocentromere. The available examples of centromere inactivation suggest a common scenario accompanying their silencing. The strong constraint against recombination acting on normal centromeres progressively weakens following inactivation. Very likely, nonallelic homologous exchanges trigger a rapid elimination of satellite DNA, while pericentromeric duplications are dispersed over a longer range, up to 10 Mb in size. Similarly, evolutionary neocentromeres rapidly progress toward the “normal” complex organization typical of a mammalian centromere: they acquire a large block of centromeric heterochromatin and pericentromeric segmental duplications.

Neocentromeres are fully functioning centromeres that are formed ectopically, most frequently on acentric fragments generated as a result of cytogenetic rearrangements whose mitotic survival was rescued by neocentromere activation. The first well-documented neocentromere case was described in 1997, on chromosome 10 (du Sart *et al*., 1997). Since then, more than 50 neocentromeres have been described, many of which are clustered in clear hotspots, like the one at the region 15q24-26 (Amor and Choo, 2002). The evolutionary history of the ancestral 14/15 association disclosed an ancestral centromere that inactivated about 25 million years ago, after the great apes/Old World monkeys diverged. This inactivation has followed a noncentromeric chromosomal fission of an ancestral chromosome, which gave rise to phylogenetic chromosomes 14 and 15. Mapping of the ancient centromere and two neocentromeres in 15q24-26 established that the neocentromere domains map to duplicons, copies of which flank the centromere in Old World

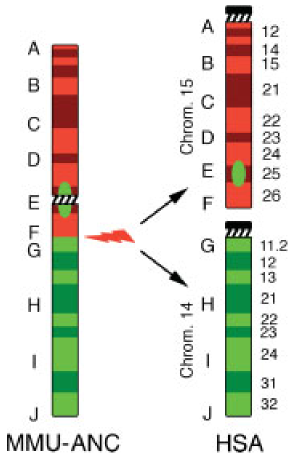

Figure 4 The diagram shows the evolutionary history of the ancestral 14/15 association. A fission event, which occurred about 25 million years ago, gave rise to chromosomes 14 and 15. The ancestral 14/15 association is conserved in macaque (*Macaca mulatta*, MMU). The event triggered the birth of two neocentromeres and the inactivation of the old centromere. Letters on the left are probes (BAC clones) used to define marker arrangement along the chromosomes

Monkey species that bear the ancestral 14/15 association (Figure 4) (Ventura *et al*., 2003). This suggests that the neocentromere at 15q24-26 may be due to the persistence of duplications accrued within the ancient pericentromere.

This is the first clear sample of an association between neocentromeres and ancestral centromeres. At present, we have a very rough picture of the evolutionary history of human chromosomes. Future studies are very promising in further clarifying this intriguing connection.

Short Specialist Review

Transcriptional promoters

Wyeth W. Wasserman
University of British Columbia, Vancouver, BC, Canada

1. Introduction

Transcription, the first step in the flow of genetic information from DNA to RNA to protein, acts as the gatekeeper controlling the influence of genes upon the phenotype of cells. When the three-dimensional structure of chromatin and the presence of appropriate catalytic proteins are permissive, biochemical protein machinery is assembled within regions of genes termed promoters. While this summary is focused on human gene transcription, and more specifically to transcription mediated by RNA polymerase II, the properties of transcription in other systems will be briefly addressed.

2. Biochemistry of transcript initiation

The biochemical mechanisms of transcription of human protein-coding genes by RNA polymerase II are among the most closely studied of any cellular process. As such the process is richly described in dedicated textbooks (Latchman, 2003) and detailed review articles (Butler and Kadonaga, 2002).

Cis-regulatory elements in the promoter of a gene are bound by trans-acting proteins (Figure 1). These elements can include the broadly recognized TATA box sequence that frequently occurs approximately 30 bp before a site of transcript initiation (the Initiator site), as well as the common downstream promoter element. At these core elements, the basal machinery of transcription is formed, including such basal protein complexes as TFIIA, TFIIB, and TFIID. Studies have revealed diverse gene-to-gene variation in the specific characteristics of transcript initiation, so individual promoters may be composed of different combinations of the elements (and consequently more dependent upon specific subsets of trans-acting proteins). There are indications that some of the trans-acting proteins act in specific cellular contexts, in a manner similar to the "sigma" proteins that control transcription in bacteria (Hochheimer and Tjian, 2003). For clarity, there is no absolute requirement for either an upstream TATA element, the Initiator element, or for the downstream element.

On the basis of the characteristic elements, minimal promoters are often attributed to the region from −50 bp to +50 bp on either side of the transcription start site.

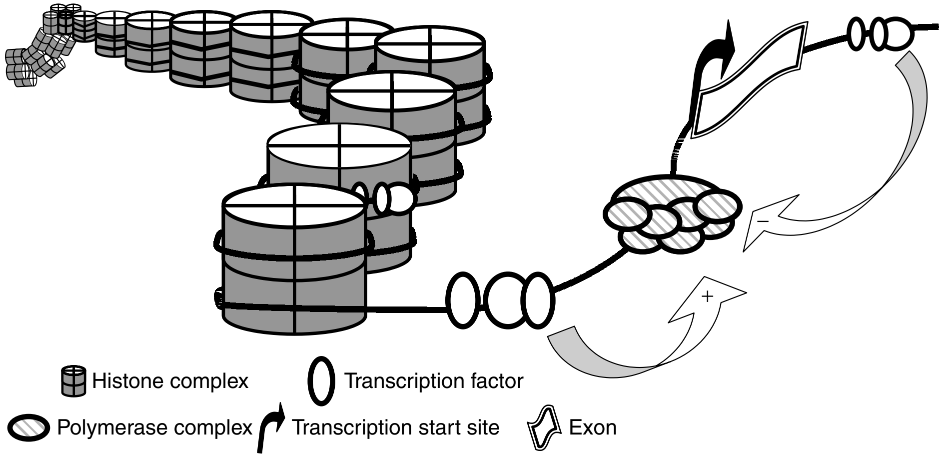

Figure 1 Transcriptional promoters: Transcription rates are defined by the activation and repression signals from regulatory modules composed of clusters of transcription factors bound to DNA. While illustrated as naked DNA, the true biochemical mechanisms occur in the context of higher orders of histone-DNA chromatin structure

However, in recent years, it has become apparent that many genes, particularly genes lacking a strong consensus TATA motif, have multiple transcription start sites within the same promoter, destroying the paradigm of the +1 position.

Of equal importance to local cis-regulatory sequences are epigenetic regulatory mechanisms governing the structure of chromatin. DNA in active regions of transcription can be subject to distinctive patterns of methylation (*see* Article 32, **DNA methylation in epigenetics, development, and imprinting**, Volume 1). Within intrapromoter regions, methylation is substantially reduced compared to the rest of the human genome. As methylated cytosines (on ring position five) 5′ to guanine nucleotides tend to undergo deamination to form a TG dinucleotide, there is a strong selection against CG dinucleotides throughout much of the genome. In many promoter regions, trans-acting proteins act to maintain an open chromatin conformation by altering methylation, which results in a higher retention of CG dinucleotides within these promoter regions. Not all promoters are linked to the retention of CG dinucleotides, and there are some indications that promoters with CG signatures tend to utilize a wide range of initiation sites (Butler and Kadonaga, 2002).

3. Genomics and promoter identification

The identification of promoter locations (*see* Article 22, **Eukaryotic regulatory sequences**, Volume 7) is critical to deciphering the regulatory programs of cells. Most sequence-specific transcription factors bind to regulatory elements proximal to promoters (Hannenhalli and Levy, 2001), so detailed analysis of regions flanking promoters (*see* Article 16, **Searching for genes and biologically related signals in DNA sequences**, Volume 7) can reveal important insights into the biochemical mechanisms governing expression. Furthermore, many genes contain alternative

promoters, which can contribute to the creation of different open reading frames directly or indirectly via promotion of specific alternative splicing events. Thus, the identification of functional promoters in the human genome remains an imperative.

Techniques for promoter identification have matured. Traditionally, molecular methods have relied on the identification of the longest transcript based on the creation of complementary DNA (cDNA) replicates of mRNA. Such methods have included run-on assays with oligo priming followed by extension by reverse transcriptase, and more recently by PCR with long cDNA collections in a process termed RACE. These methods are constrained by the capacity of the reverse transcriptase enzyme to successfully produce full-length DNA copies; however, the enzyme is easily blocked by RNA structure. Thus, most cDNAs do not extend to the original 5′ terminal position.

On the basis of the 5′ terminal cap structure of mRNA, a new technique using an antibody to recognize the cap has been developed to recover full-length transcripts (Okazaki *et al*., 2002). Originally applied to the generation of full-length cDNA copies, the method has recently been modified to allow for the recovery of 5′ terminal tags in a process analogous to serial analysis of gene expression (SAGE) (*see* Article 103, **SAGE**, Volume 4), a new method termed cap analysis of gene expression or CAGE (Shiraki *et al*., 2003). Early observations from these high-throughput studies indicate that many genes are transcribed from a pool of start sites spread over the promoter region.

The specific TSS is determined by the constraints upon the polymerase complex – TATA and DPE contribute to positioning – when they are well defined, a single TSS is primarily used, however, if they are not well defined, a stochastic positioning of the polymerase results in a wide range of TSS. In short, the PCR-based RACE techniques give misleading indications that the 5′ most position of a transcript is of the greatest importance, while such positions may be rarely used for initiation in the case of a stochastic process.

4. Bioinformatics methods

Bioinformatics-based approaches for promoter identification (*see* Article 19, **Promoter prediction**, Volume 7) loosely fall into three categories: ab initio prediction (*see* Article 66, ***Ab initio*** **structure prediction**, Volume 7) of specific transcription start sites; identification of regions in a genome likely to contain promoters; and mapping of known transcripts onto genome sequences.

On the basis of the properties of regulatory elements in minimal promoters, a diverse set of algorithms has been created for the ab initio prediction of initiation sites. A broad assessment (Fickett and Hatzigeorgiou, 1997) demonstrated that the performances of most algorithms were comparable to predictions of TATA elements generated with a position-specific scoring matrix (PSSM) (Bucher, 1990). The PSSM models the binding preferences for the TATA Binding Protein, generating a single quantitative score that is analogous to binding energy. The TATA profile renders a prediction on the order of one per 500 bp, providing little motivation to conduct laboratory experiments based solely on a prediction. The poor predictive performance of the transcription start site prediction methods reflects the diversity

of promoter structures and the above-mentioned observation that many promoters contain multiple initiation sites.

A new generation of bioinformatics algorithms address a slightly different goal, the identification of regions in a gene likely to contain promoters. These tools have proved highly successful in identifying the likely promoter regions in genes. While the implementation details vary widely, the algorithms generally identify CpG islands within a gene; those regions containing CG dinucleotides at the expected frequency based on the mononucleotide frequency of G and C. These methods perform poorly for the prediction of promoters that do not have associated CG retention.

Ultimately, the best methods for promoter identification are based on transcript data (Bajic *et al*., 2004). The compilation of CAGE data, EST sequences (*see* Article 78, **What is an EST?**, Volume 4), and full-length transcripts are rapidly building to a robust repository. The reference database dbTSS (Suzuki *et al*., 2004), which combines evidence from diverse transcripts, has emerged a primary source of human promoter data.

5. Considerations in other systems

Transcription by human polymerase II is merely one example of the range of transcription mechanisms used across organisms. In particular, operons are used extensively (*see* Article 20, **Operon finding in bacteria**, Volume 7). By producing multiple genes in a single polycistronic transcript, bacteria can minimize the need for regulatory control sequences while ensuring that genes that act together are produced concurrently.

In yeast, most regulatory sequences are located in close proximity to the transcribed gene and introns are not present; most promoters can be predicted simply by identifying open reading frames and selecting sequences adjacent to promoters.

6. Future

The activity of promoters is determined by a combination of DNA accessibility and the influence of trans-acting activator proteins. Our understanding of the structural constraints on promoters remains limited. Present research is suggesting that active genes may have regulated positions in the nucleus that influence activity. As well, there is growing evidence of a complex set of silencing mechanisms to maintain many promoters in an inactive state. The relationship between three-dimensional structure and promoter activity will be revealed in the coming years.

Finally, there is growing evidence of extensive variation between individuals in the expression of genes. Genetic sequence variation (*see* Article 68, **Normal DNA sequence variations in humans**, Volume 4) within promoters could have dramatic influence on the activity of promoters, and likely contributes to phenotypic diversity.

Short Specialist Review

Human microRNAs

Sam Griffiths-Jones
The Wellcome Trust Sanger Institute, Cambridge, UK

1. Introduction

In 2001, three groups published independent reports of the discovery of a large class of tiny noncoding RNAs (ncRNAs, *see* Article 27, **Noncoding RNAs in mammals**, Volume 3) in worm, fly, and human (Lagos-Quintana, 2001; Lee, 2001; Lau, 2001). The ncRNAs were named microRNAs (miRNAs) and the reports generated widespread interest. The founder member of the miRNA class had been identified some years earlier: the *lin-4* gene controls the timing of *Caenorhabditis elegans* larval development. Ambros and colleagues showed that *lin-4* codes for two small RNA products, one around 22 nucleotides (nt) in length, and the second around 60 nt (Lee, 1993). The latter was proposed to be a precursor for the shorter sequence. Further work showed that the mature lin-4 RNA was able to bind complementary regions of the lin-14 mRNA to repress its translation (Wightman, 1993; Lee, 1993). Ideas that lin-4 was an anomaly, specific to the worm, were dispelled by the identification of a second short RNA, let-7, found to regulate the transition from late-larval to adult in *C. elegans* (Reinhart, 2000). let-7 was found to be widely conserved in humans, flies, and many other bilateral animals (Pasquinelli, 2000). Subsequent discoveries have put the total number of known miRNAs in worms, flies, mammals, fish and plants above 1000, many of which have been shown to be expressed in tissue specific patterns (reviewed in He, 2004). miRNAs are implicated in gene regulatory roles in processes as important and diverse as development, fat metabolism, and oncogenesis (reviewed in Bartel, 2004; Ambros, 2004).

I briefly summarize the current understanding of miRNA biogenesis and message targeting – the reader is directed to many excellent review articles cited here for more in-depth coverage of these topics. This review then focuses on the human miRNA gene complement, with emphasis on conservation and gene organization.

2. Biogenesis and target regulation

Maturation from primary transcript to mature miRNA has been thoroughly characterized over the past two years (see Figure 1). The mature miRNA (often designated miR), around 21 nt in length, is excised from a larger precursor transcript (around

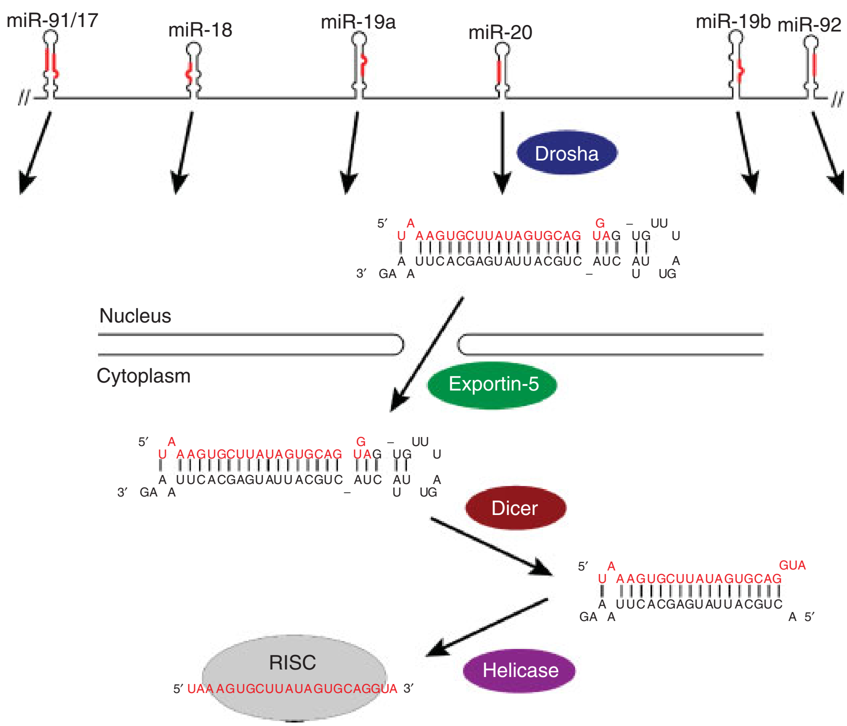

Figure 1 Summary of the biogenesis of a miRNA cluster (see text for description of processing steps)

70 nt in animals), which adopts a hairpin conformation by intramolecular base pairing. Usually, only one arm of the hairpin gives rise to a mature miRNA sequence. The opposite arm, designated miR* is sometimes observed at a lower frequency in cloning studies. The precursor hairpin (termed pre-miRNA) is itself processed from a larger primary transcript (termed pri-miRNA), which may be kilobases in length. The first processing step of pri-miRNA to pre-miRNA is catalyzed by an RNase III endonuclease, DROSHA, in the nucleus, and defines one end of the mature miR (Lee, 2003). The excised precursor is exported to the cytoplasm by exportin-5 (Kim, 2004) where the other end of the mature ~21 nt miRNA is cut by DICER, another RNase III endonuclease (Lee, 2002). The resulting miR/miR* duplex has a characteristic two nucleotide 3′ overhang at each end. The duplex is unwound by an unknown helicase before the mature miR is recruited into the RNA-induced silencing complex (RISC), which targets it to complementary sequences in untranslated regions (UTRs) of other mRNAs. The current hypothesis is that miRNAs may have two modes of action, depending in part on the degree of complementarity to the target regions in the message. Exact base pairing causes the messenger transcript to be degraded by RNAi, while more extensive mismatching causes translational repression (reviewed in Meister, 2004). Only a handful of mammalian miRNA targets have been experimentally confirmed (reviewed in Ambros, 2004; He, 2004).

3. Human miRNA genes

The miRNA Registry (Griffiths-Jones, 2004) provides a catalog of experimentally determined miRNA sequences and their predicted homologs in closely related organisms. At the time of writing, over 200 miRNA genes have been discovered in human, mouse, and rat, giving rise to around 190 unique mature miRNAs. Well over half of these sequences have experimental evidence of expression in human cell lines. Some miRNAs are expressed from several hairpin precursors, transcribed from different genomic loci.

By statistical analysis of the results from computational predictions and cloning studies, Lim *et al*. (2003) have estimated the total number of miRNA genes in the human genome to be not more than 255. Although this is perhaps fewer than expected, miRNAs still account for around 1% of the total human gene count, in similar proportions to some other large regulatory gene families, such as homeobox transcription factors and KRAB box zinc fingers (International Human Genome Sequencing Consortium, 2001). This also suggests that, in a very short space of time, the experimental biologists have identified well over three-quarters of the mammalian miRNA gene complement. However, if a subset of miRNA genes proves difficult to clone, perhaps due to low abundancy or specific spatial or temporal expression, and is missed by computational prediction methods, the total number of human miRNAs may eventually be shown to be larger.

The comprehensive nature of the known miRNA set has encouraged the first analyses of genomic contexts and cross-species conservation. The data show that a small number of miRNAs, including let-7, are well conserved from worms and flies through fish, birds, and mammals (Pasquinelli, 2000). Almost all human miRNAs are conserved in order and orientation in the mouse and rat genomes, and nearly 40% map to syntenic regions of the draft chicken genome (International Chicken Genome Sequencing Consortium, 2004). This seems to be in contrast with other classes of ncRNAs, such as the spliceosomal RNAs, whose genes have not been well conserved in syntenic regions of even very closely related genomes.

4. miRNA gene structure

Examining the genomic context of miRNA sequences shows a variety of gene structures and may suggest subtly different methods of biogenesis. The first miRNA reports demonstrated that some genes are arranged in clusters – in *C. elegans*, seven miRNA genes, numbered miR-35 through miR-41, cluster within 1 kb on chromosome II (Lau, 2001). It is suggested that such clustering may be indicative of polycistronic expression, with seven miRNAs processed from the same primary transcript. Indeed, the first primary transcript to be thoroughly characterized contains three mammalian miRNAs: miR-23a, miR-27a, and miR-24 (Lee, 2004). This work experimentally confirms previous predictions that miRNA genes are transcribed by RNA polymerase II (pol II), and that the primary transcripts are, like protein-coding messages, capped and polyadenylated. Moreover, the miR-23a∼27a∼24 primary transcript is long – almost 2 kb. Analysis of the human miRNA set shows that as many as 70 miRNA genes are located within 2 kb of another miRNA, and are

thus candidates for coexpression from the same transcript. The arrangement of the largest cluster of six miRNAs in human is shown in Figure 1. The evolution of this cluster has been the subject of detailed investigation: mammals appear to have three paralogous copies of the miR-17 cluster – on chromosomes 13, X, and 3 – while fish genomes contain four copies (Tanzer, 2004).

The second major class of miRNAs are processed from the introns of other transcripts, usually coding for proteins, but sometimes for noncoding RNAs. As many as 80 human miRNAs are located in introns of annotated protein-coding transcripts (Rodriguez, 2004), usually in the sense orientation, implying utilization of host gene transcription rather than dedicated promoter sequences. Embedding in a host transcript provides a convenient mechanism for coordinate expression of miRNA and protein. Many of the hosts fall into paralogous gene families (Weber, 2005). For example, the human genome contains four pantothenate kinase genes, numbered PANK1 to PANK4. miR-103 appears to be expressed from two predicted stem-loop precursors, located in intron 5 of both PANK2 (chr 20) and PANK3 (chr 5). Intron 5 of PANK1 (chr 10) contains the closely related miR-107. No experimentally confirmed miRNA overlaps the PANK4 transcript. Other miRNAs may be expressed from unrelated hosts, complicated further by different tissue expression profiles. For example, miR-7 has three predicted genes in the human genome. miR-7-3 is located in an intron of *pituitary gland specific factor 1*, a gene expressed exclusively in the pituitary gland (Rodriguez, 2004). An alternative precursor locus is located in an intron of a ubiquitously expressed gene, *heterogeneous nuclear ribonucleoprotein K* (*hnRPK*), in an miR/host gene relationship that is conserved in *Drosophila* (Bartel, 2004). miR-7-2 does not overlap any annotated transcripts and thus may be expressed from its own promoter under different regulatory conditions. The three *mir-7* gene contexts are shown schematically in Figure 2. Almost all identified human miRNA/host gene relationships are conserved in mouse and rat.

A number of miRNAs may also overlap with annotated mRNA-like transcripts that do not appear to code for a protein (Rodriguez, 2004). miR-15a and miR-16 are located in the same intron of the well-annotated DLEU2 noncoding transcript, in a region implicated in B cell chronic lymphocytic leukemias (CLL). The intron-encoded miRNAs have been shown to be deleted or downregulated in more than two-thirds of CLL cases (Calin, 2002). miR-206 appears to be transcribed as part of the longer 7H4 transcript, which is selectively found at the neuromuscular junction (Velleca, 1994). The data suggest that some miRNA host genes may be so-called inside-out genes, where the host transcript is expressed purely to yield the processed RNA from the introns, similar to some small nucleolar RNAs.

5. Conclusions

The past three years have seen staggering advances in our understanding of miRNAs, their genes and biogenesis. Estimations of gene counts suggest that experimental verification, sometimes effectively combined with computational prediction, have revealed the majority of miRNA genes in a number of model organisms, including in mammals, in an incredibly short space of time. Recent studies also shed light on the implications of miRNA discovery on the complexity of gene

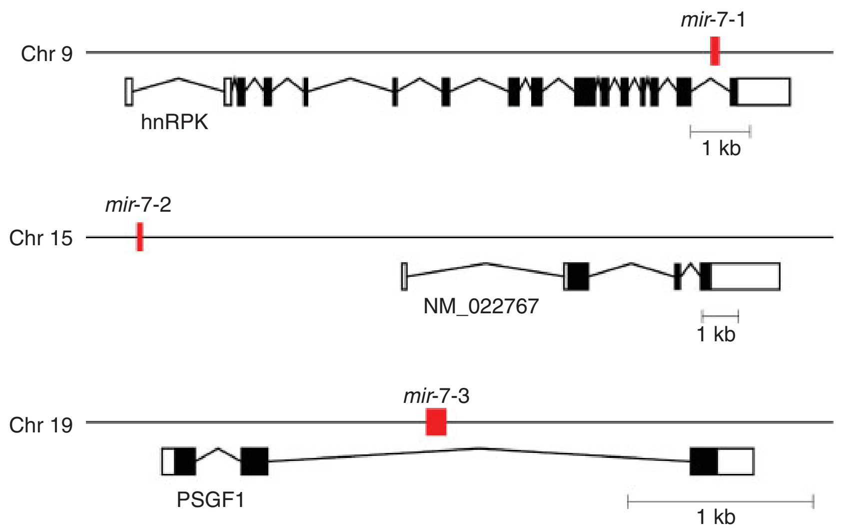

Figure 2 The three human *mir-7* genes on chr 9 (82.04 Mb, reverse strand), chr 15 (86.88 Mb), and chr 19 (4.72 Mb). All sequences are depicted from the 5′ to the 3′ end. The transcripts shown are *heterogeneous nuclear ribonucleoprotein K* (*hnRPK*), a putative nucleolar exonuclease (REFSEQ: NM_022767), and *pituitary specific growth factor 1* (*PSGF1*). Black boxes are exons, open boxes show untranslated regions. The miRNA precursor hairpin is shown in red

regulation, especially during development. A number of disease states, including some cancers, may yet involve miRNAs.

The diversity of miRNA gene structures provides some tantalizing examples of genes with distinct and parallel output, and hints at complex regulatory networks. A long primary transcript may express a single miRNA or multiple distinct miRNAs in a polycistronic cluster. The same transcript may also encode a protein, or a spliced mRNA-like noncoding RNA. miRNAs expressed from autonomous transcripts or coexpressed with a protein may then regulate the expression of a wide range of genes, possibly including other miRNA host genes; clustered miRNAs may coordinately regulate the same targets, or participate in different pathways. The same mature miRNA may originate from multiple genomic loci, under independent regulatory control, and it is also clear that any single targeted message may be regulated by more than one miRNA. Alternative splicing of host transcripts is likely to add a further layer of complexity to the story. These findings have fundamental implications for our understanding of what constitutes a gene, and how parallel output may be involved in vital regulatory mechanisms. We can expect the next three years to see equally significant advances in understanding of gene regulation by this extraordinary class of ncRNA, as their targets are identified and described.

6. Data sources

Discussion of miRNA gene counts and genomic arrangement is based on data from the miRNA Registry, release 5.0 (**http://www.sanger.ac.uk/Software/Rfam/**

mirna/). Genome assemblies and gene predictions relate to EnsEMBL human build 24.34e.1 and mouse build 24.33.1, available from (**http://www.ensembl.org/**).

Short Specialist Review

Endogenous retroviruses

Jens Mayer
University of Saarland, Homburg, Germany

Vertebrate genomes harbor considerable sequence portions of retroviral origin that are stably inherited genome components. Retroviruses typically infect somatic cells of a host organism. They reverse transcribe their RNA genome to double-stranded DNA, and integrate the DNA into the host cell genome, forming a so-called provirus, that serves to produce RNA transcripts and retroviral proteins for further infectious virus. In the evolutionary past, different retroviruses formed proviruses in the genome of germ-line cells. Since germ-cell genomes comprise the inherited genetic material and are precursors to somatic cells, incorporated proviruses could have been transmitted through generations and became part of somatic cells. The stably inherited proviruses are called *endogenous retroviruses* (ERVs). During evolution, ERVs were also transmitted to new species. In most cases, exogenous counterparts of ERVs are no longer present.

ERVs often resemble the former exogenous retrovirus proviral structure. Two long terminal repeats (LTRs) enclose *gag*, *protease*, *polymerase*, and *envelope* genes. The LTRs represent autonomous units for transcription regulation, initiation, and termination, while retroviral genes produce structural proteins and enzymatic activities required during retroviral replication. Owing to the long-time presence in the host genome, ERVs often accumulated nonsense mutations, rendering them coding-deficient and transcriptionally silent. Mutational events often deleted considerable portions of proviral genes. Several exceptions exist regarding transcriptional activity and coding-capacity, though (see below). Furthermore, proviruses were frequently reduced to so-called "solitary LTRs" by homologous recombination between proviral 5′ and 3′ LTRs. Solitary LTRs regularly outnumber the actual provirus count for a given ERV family by far (Gifford and Tristem, 2003).

Distinct ERV families can be identified in a genome. Members of a family are more similar in sequence among each other than to other ERV families. Thus, endogenization of diverse exogenous retroviruses occurred many times during evolution. Most ERV families subsequently increased proviral copy numbers in the host genome, that is, additional proviruses formed after initial provirus formation, and were likewise fixed in the population. It is thought that retroviral RNA was transcribed from a proviral element and was subsequently reverse transcribed and integrated into the same genome. Some ERV families expanded to several thousand proviral copies that way. Formation of new proviruses seems very low or does not occur in humans. Differences in proviral integration patterns can only be observed

on an evolutionary timescale. Various human proviruses are missing in, for instance, the chimpanzee genome, that evolutionarily separated about 5 million years ago (Buzdin *et al*., 2002). The mouse genome seems to hold more active ERV families, and some proviral loci in the mouse can be expressed as infectious virus. A recent analysis estimated approximately 10% of the mouse genome to be of retroviral origin (Mouse Genome Sequencing Consortium, 2002; *see also* Article 47, **The mouse genome sequence**, Volume 3).

The human genome harbors a variety of endogenous retroviruses, commonly referred to as HERVs (for human ERVs), that were studied to some extent. In fact, 8% of the human genome mass is estimated to be derived from retroviral sequences (International Human Genome Sequencing Consortium, 2001). This portion includes retroviral sequence families composed of more or less intact proviruses (HERVs in sensu strictu), and families with HERV sequence portions. The latter are exemplified by SINE-R (a short interspersed repeated sequence and a longer HERV portion) and SVA elements (a composite retrotransposon containing SINE-R portions, a variable number of tandem repeats, and an Alu element). Manifold HERV families were identified in the past by various means; cross-hybridization with exogenous retrovirus probes, isolation of HERV RNA transcripts, degenerated primers, proviral sequence characteristics, and so on. Although there is no standardized nomenclature, HERV families are often named according to the amino acid specificity of the tRNA that primed reverse transcription of retroviral RNA by binding to the primer binding site (PBS). The tRNA's corresponding amino acid single letter code is appended to HERV. Recent surveys cataloged between 30 and 50 HERV families. The widely employed reference sequence database for repetitive elements, Repbase, lists more than 200 different HERV and LTR families (Jurka, 2000; *see also* Article 9, **Repeatfinding**, Volume 7). It appears that many HERV sequences and families await more detailed genomic characterization. Various HERV families were found to have entered the genome before the separation of existing primate lineages and species; about 30–40 million years ago. Other HERV families appear much older, as homologous sequences are also found, for instance, in the mouse. Evolutionary ages of ERVs can be estimated from sequence divergence between a provirus' 5′ and 3′ LTRs. They were identical in sequence when the provirus formed and accumulated random sequence mutations over time (Dangel *et al*., 1995). Alternatively, specific probes may be employed in hybridization experiments to identify ERV family-positive evolutionary clades.

There is strong experimental evidence of ERVs having profoundly impacted host genomes during evolution as a result of proviral amplification. One aspect concerns the influence on cellular genes when proviral LTRs – autonomous transcriptional units – integrated in close proximity (*see* Article 33, **Transcriptional promoters**, Volume 3). Several instances were revealed in the human genome where HERV LTRs act as major or alternative promoters for cellular genes, provide poly-A or splice signals (*see* Article 30, **Alternative splicing: conservation and function**, Volume 3 and Article 23, **Alternative splicing in humans**, Volume 7). HERV sequence portions are then present in cellular mRNAs. As an example, an HERV LTR is the dominant promoter for human β1,3-galactosyltransferase gene expression in the colon (Dunn *et al*., 2003). When positioned in close proximity to gene

promoters, LTRs may also act as transcriptional enhancers or suppressors, owing to their inherent transcription factor binding sites. Very likely, similar studies in the mouse will reveal mouse genes affected by mouse ERVs.

ERV-encoded proteins can also provide important functions for host organisms. Two ERV-derived genes, *Fv-4* and *Fv1*, have been identified in the mouse to effectively block infection and provirus formation, respectively, of specific exogenous retroviruses (Best *et al*., 1997). At least one HERV protein may be involved in physiological processes in human. In the developing placenta, expression of the HERV-W Env protein strongly increases during fusion of trophoblasts, forming a syncytiotrophoblast layer. HERV-W Env also fuses cell membranes when expressed in cell culture, thus producing syncytia. HERV-W Env therefore may be crucially involved in human placenta development (Blond *et al*., 2000). Remarkably and hitherto unexplained, the so-called HERV-K(HML-2) family propagated intact retroviral genes and functional proteins among its proviruses for several million years (Mayer *et al*., 1999). Antibodies specific for HERV-K(HML-2) Gag and Env proteins are frequently present at higher levels in germ cell tumor patients, potentially serving as a molecular marker for that tumor type (Sauter *et al*., 1996). The HERV-K(HML-2) encoded Rec protein associates with the promyelocytic zinc finger protein and may be involved in germ cell tumorigenesis (Boese *et al*., 2000).

Taken together, ERVs are important genome components. They boarded the host genome at one time period in evolution and often considerably amplified in copy number within the genome. By doing so, they affected the genome in diverse aspects and thus contributed significantly to the evolution of host genomes.

Genome archaeology

Samuel Aparicio
University of Cambridge, Cambridge, UK

1. Introduction

The availability of substantially sequenced animal genomes in the last 5 years has served as the framework not only for studies of individual genes, but has allowed much greater insight into the evolution of content and structure. Also at a very practical level, the availability of completed genomes has transformed the speed at which both evolutionary and functional studies can be undertaken – large amounts of time and effort that historically were spent on simply cloning a desired gene to study its sequence or mutate it, for example, are now entirely bypassed. Conceptually, the ability to compare long contiguous sequences directly (as opposed to inferring content from indirect studies of nucleic acids), and to know the entire contents of a given genome, has permitted more precise conclusions. The human (Lander *et al.*, 2001; Venter *et al.*, 2001), mouse (Waterston *et al.*, 2002; *see also* Article 47, **The mouse genome sequence**, Volume 3), pufferfish (Aparicio *et al.*, 2002; *see also* Article 46, **The Fugu and Zebrafish genomes**, Volume 3), and recently chicken genomes (Hillier *et al.*, 2004), have added considerable depth to the annotation of protein-coding gene loci and noncoding regulatory and structural elements. The basis for all such comparisons is that unconstrained sequences are quickly randomized by mutations, and thus the presence of conserved sequence elements over large distances strongly implies conserved function. The value of comparing multiple vertebrates has thus become realized. Outlined here are some of the key questions that have been or are being addressed at a macrogenomic scale from the genome-sequencing programs of metazoans.

2. Evolution of content

There are two major questions: how many gene loci are there in a given organism and what mechanisms have accounted for the numbers of gene loci. The question of the number of gene loci in a given organism is one of the oldest questions, and this has yielded to whole-genome sequencing. Before sequencing of complex animal genomes was initiated, estimates ranged widely, especially for humans, where the predictions ranged from 25 000 gene loci to over 140 000. Comparative genomics of partially sequenced genomes provided (Aparicio, 2000; Ewing and

Green, 2000; Roest Crollius *et al*., 2000) a good guide to this almost a year before the draft sequencing of humans announced the ballpark result of 30 000–35 000 loci – much fewer than what most people had predicted. Even this turned out to be an apparent overestimate – as the annotation of genomes has improved, the number of gene loci has drifted downward, currently to around 25 000 for humans, although recent methods (Bertone *et al*., 2004) of detecting rare transcripts suggest that the number may yet be revised upward again – but only by a small percent. The figure of approximately 25 000 should be compared with invertebrate metazoans, for example, flies and worms in which the gene content was found to be between 12 000 and 18 000 genes approximately (*see* Article 44, **The *C. elegans* genome**, Volume 3 and Article 45, **The *Drosophila* genome(s)**, Volume 3). Estimates for teleost fishes from completed genomes (Aparicio *et al*., 2002; Jaillon *et al*., 2004) at the base of the vertebrate tree are similar to those of humans. Clearly, the leap from invertebrates to vertebrates did not result in expansion of more than about one-third of the total gene complement. However, whole-genome sequencing has made it clear that substantial evolution has taken place within gene families and, crucially, to the means by which gene expression is controlled (see following text), suggesting that the apparent complexity of mammals has as much to do with these mechanisms as with increases in the total number of gene loci.

Related to the number of gene loci has been considerable insight into the processes by which the number of genes has increased through evolution. Several mechanisms are thought to have influenced this process, principally, tandem gene duplication, retrotransposition of genes, and whole-genome (or chromosomal) duplication. The process of whole-genome duplication is thought to occur via the existence of a chromosomally polyploid ancestor, which (by mechanisms presently not understood), fixes its chromosome complement in a diploid state, thus doubling the gene complement of a given lineage. While genome duplication is therefore the most far-reaching mechanism in sheer scale, it has also been the hardest to detect, because gene duplicates tend to be rapidly eliminated during evolution, unless fixation occurs through selective processes. Sequencing of yeasts and the worm provided early evidence that these organisms were degenerate polyploids (organisms that have experienced a round of genome duplication, followed by extensive loss of duplicate genes). The proposal by Ohno, that the content of vertebrate genomes had been shaped through successive rounds of genome duplication, was therefore a subject of some controversy until substantially completed fish and mammal genomes became available. The availability of these genomes has shown first that vertebrates certainly underwent one round of genome duplication, or possibly two. Second, it has also become clear that teleost fishes, a vertebrate subfamily, also underwent an additional round of genome duplication close to the time of their origin (Amores *et al*., 1998; Christoffels *et al*., 2004; Van de Peer, 2004). Duplication events were identified in both of these cases, by searching for linked groups of orthologous genes in which the linkages were shared between distant vertebrate species. Molecular phylogenetic dating methods applied to these clusters established the approximate timing of these events. Although attempts had been made at such analyses before the availability of sequenced genomes, it had proven difficult to establish a sufficient number of linkage groups with orthologous genes.

Evolution of protein-coding families has also become apparent as the result of genome-wide comparisons, for example, the selective expansion of olfactory receptor GPCRs in rodents, the expansion of immune receptor families in mammals, and the (unexplained) excess of kinase proteins in teleosts. Comparisons between vertebrate genomes have revealed how genomic structural elements such as repetitive elements have evolved. For example, when humans and fugu were first compared, it became clear that while humans have a much greater proportion of repetitive DNA sequences, these are mostly of a restricted class, retrotranscribed repeats capable of endoduplication and reinsertion around the genome. Fugu, however, have a much greater diversity of repetitive DNA sequences, with almost every described class of metazoan repeat sequence represented – but collectively, these sequences comprise less than 15% of the genome, as opposed to 40% in humans. The evolutionary and functional significance of this observation remains unclear.

3. Evolution of function

As implied above, evolved complexity has arisen not only from the number and types of gene loci encoded, but from increasingly complex regulation of gene expression. Comparisons of genomes show that this happens at multiple levels, from regulation of alternative splicing, through the mechanisms of transcriptional modification and posttranslational modification. Detecting regulatory signals in the genome is much harder, in part because no equivalent of linear code exists for these and partly because the signal elements are, for the most part, made of small degenerate sequences combined together. Comparisons of noncoding sequences were proposed many years ago as one means of detecting these elements, and such comparisons are now revealing the locations of regulatory sequences (*see* Article 48, **Comparative sequencing of vertebrate genomes**, Volume 3). Genome-wide comparisons have revealed both conserved and novel regulatory functions. A recent finding has been the presence of very highly conserved noncoding sequence regions between distantly related vertebrates (Bejerano *et al*., 2004)

For example, in the last 5 years, antisense RNA regulation has gained prominence in vertebrates, as a mechanism that may regulate gene expression. The encoding of antisense RNAs and micro-RNAs as potential regulatory features has recently been shown to be conserved amongst vertebrates (Lim *et al*., 2003). Although the exploration of the functions of micro-RNAs is still in its infancy, the fact that they are conserved as elements in genomes separated by 450 Myr of evolution strongly suggests that they are required.

In contrast, other mechanisms appear to be vertebrate specific – while measures of splicing complexity are still controversial, it is clear that vertebrates have expanded tissue-specific core spliceosome elements (hnRNP and SR proteins) in comparison with invertebrates. Promoter CpG island methylation is known to be a vertebrate feature (as distinct from methylation of viral DNA sequences that occur in all species), and the complexity of this regulation increases from basal vertebrates to mammals (epigenetic imprinting is thought to be specific to placental mammals, for example). Not surprisingly, the content of gene families effecting some of these functions has coevolved.

4. Conclusion

We are at the cusp of a new discipline delving into the science of genomes. We can expect the diversity of sequenced animal genomes to increase substantially over the coming years. The availability of additional sequenced genomes will allow us to further elaborate our understanding of both genome content and function, and provide enormous opportunities for elaborating our understanding of the evolution of the animal kingdom.

Introductory Review

Functional analysis of genes

Rick Woychik and Carol Bult
The Jackson Laboratory, Bar Harbor, ME, USA

1. Introduction

The Human Genome Project started a revolution in biology. The initial effort to sequence the genomes of humans and many model organisms is now essentially complete (*see* Article 43, **Functional genomics in *Saccharomyces cerevisiae***, Volume 3, Article 44, **The *C. elegans* genome**, Volume 3, Article 45, **The *Drosophila* genome(s)**, Volume 3, Article 46, **The Fugu and Zebrafish genomes**, Volume 3, and Article 47, **The mouse genome sequence**, Volume 3). Researchers can now use numerous Internet resources and databases to access the annotated genomes of human, the laboratory mouse, yeast, Drosophila, and many other organisms. These electronic catalogs of genes with their associated nucleotide and protein sequences serve as a powerful launching off point for experimental and computational approaches to understanding the biological role and function of genes and gene products.

One of the most powerful ways of studying the function of a gene is to alter its expression within an organism. Indeed, analyzing changes in the expression of a gene to study its biological function in vivo has become a mainstay in biological research. If the expression of a gene is changed in a specific way (e.g., knocked out) and the organism develops a specific phenotype (e.g., a disease state), then a connection can be made between that gene and function in the organism.

There are many model organisms that can serve as platforms for determining gene function (*see* Article 38, **Mouse models**, Volume 3, Article 39, **The rat as a model physiological system**, Volume 3, Article 41, **Mouse mutagenesis and gene function**, Volume 3, and Article 42, **Systematic mutagenesis of nonmammalian model species**, Volume 3), although only some of these are also useful for studying gene function with genetics approaches. Here we will cover a variety of model organisms including yeast (*Saccharomyces*), fly (*Drosophila*), worm (*Caenorhabditis*), zebra fish (*Danio*), mice (*Mus*), and rat (*Rattus*). That functional homologs for most human genes can be found within these species allows researchers to translate the understanding of gene function between organisms and ultimately to humans.

Experimental genetics is commonly used to study gene function because spontaneous and induced mutations often cause changes in the expression of a gene. Mutations in or near a gene can alter the level of transcription and/or translation,

and sequence variations within the coding sequence of a gene can change the nature of the protein product. In humans, this approach to understanding gene function is limited to new spontaneous mutations. In model organisms, however, the genome can be manipulated through experimental mutagenesis, and the differential expression of genes can be used to dissect the function of genes.

2. Experimental mutagenesis

Experimental genetic approaches involve the intentional generation of new germline mutations and then screening for the phenotypic effects of these mutations in the organism. This approach represents one of the biggest advantages of using model organisms over studying humans directly. Mutations are typically created through treatment with chemicals or radiation, or through insertional or targeted mutagenesis. It is also possible to generate alterations in the expression of genes through transgenesis and a new technology called RNAi. Here we will briefly summarize these approaches.

2.1. Radiation- and chemical-induced mutations

The ability to create new mutations with radiation and chemical agents has been one of the most powerful tools for studying gene expression in most model organisms. Radiation typically produces large chromosomal rearrangements such as translocations, inversions, and deletions that remove large numbers of genes. Chemical mutagens, on the other hand, are most often chosen for their ability to produce subtle mutations within genes. Various chemical agents are available for mutagenesis, and one that is becoming increasingly popular is ethylnitrosourea (ENU) (*see* Article 38, **Mouse models**, Volume 3 and Article 41, **Mouse mutagenesis and gene function**, Volume 3). ENU usually produces single base-pair substitutions within the DNA. The advantage of a point mutagen is that a variety of different types of mutations can be generated, from amorphic alleles that completely inactivate the gene, to hypomorphic alleles with decreased levels of expression of that gene, as well as other types of mutations. To understand the full phenotypic potential of mutations on gene function, researchers often try to generate a complete allelic series for a given gene. While most methods for inducing mutations involve treatment of the whole animal, chemical mutagenesis of embryonic stem (ES) cells in the laboratory mouse has also proven to be an effective means of producing mutant mice (*see* Article 41, **Mouse mutagenesis and gene function**, Volume 3).

2.2. Insertional mutagenesis

Most organisms have species-specific mobile genetic elements that are capable of "hopping" around the genome. Many mobile elements are retroviral-like elements with long terminal repeats (LTRs) at both ends that contain strong promoter and

regulatory elements. Integration of mobile elements is known to occur throughout the genome. When the integration reaction occurs within a gene, it can change the expression of the gene, most often inactivating or substantially downregulating the expression of the gene. This form of mutagenesis is called insertional mutagenesis. When the element inserts upstream of a gene, the promoters within the element can ectopically activate the expression of the downstream gene. This is referred to as promoter insertion mutagenesis.

Experimental protocols have been developed for insertional mutagenesis with mobile genetic elements in all model organisms. One of the most widely used approaches involves the use of P-elements in *Drosophila* in a process called hybrid dysgenesis. In this case, crossing two different lines of *Drosophila* (*see* Article 42, **Systematic mutagenesis of nonmammalian model species**, Volume 3) mobilizes endogenous P-elements and efficiently creates new insertional mutations throughout the genome. Also, many spontaneous mutations in various organisms arise by insertional mutagenesis through the process of mobile genetic element hopping. The advantage of mutations created by insertional mutagenesis is that the mutant locus is "tagged" with the mobile genetic element. The fact that they are marked in this way makes it much easier to characterize the mutation at the molecular level.

2.3. Targeted mutations

Another form of experimental mutagenesis, called targeted mutagenesis, involves the creation of a new mutation within a specific gene. This approach can be used in yeast and mice (*see* Article 41, **Mouse mutagenesis and gene function**, Volume 3 and Article 43, **Functional genomics in *Saccharomyces cerevisiae***, Volume 3), but is not possible in most other organisms. With this form of mutagenesis, the germline can be changed in highly specific ways. It is possible to generate targeted mutations that range from single point mutations within a gene all the way to sizable deletions along the chromosome. It is also possible to "knock in" the coding regions of one gene downstream of regulatory elements of another gene. One of the newest advancements in the technology makes it possible to create "conditional" targeted mutations, where, for example, the gene is knocked out only in certain cell types or at certain times during development.

2.4. Transgenesis

One of the most powerful tools that has been developed in recent years involves the introduction of cloned fragments of DNA back into the genome of an organism. When the DNA fragment integrates randomly into the genome and becomes a stable heritable trait, the resulting organism is referred to as a "transgenic". This approach for studying the function of genes can be used in all the model organisms listed above, although the term "transgenic" is most often used in the context of studies with zebra fish, mice, and rats (*see* Article 42, **Systematic mutagenesis of nonmammalian model species**, Volume 3). In mice and rats, transgenics are most often produced by microinjection of DNA directly into an early stage embryo,

although infection with specially designed viral vectors is also used. The transgenic technology is used primarily for the purpose of testing the dominant effects of introducing a gene or modified gene construct into an organism. It is also used for a variety of other applications, including the introduction of large fragments of cloned genomic DNA back into the germline of the organism.

2.5. RNA interference

In recent years, a new phenomenon has been discovered that can be used to alter gene expression in a targeted fashion. The method is called posttranscriptional gene silencing (PTGS). The active molecule in PTGS is a double-stranded RNA (dsRNA) with sequence homology to a specific target gene within the cell. The target gene is silenced by selective destruction of its mRNA. This process has come to be known as RNA interference, or RNAi. Experimental approaches for using RNAi to regulate the expression of genes have been developed for all model organisms, with the most remarkable being in *Caenorhabditis elegans*. In this organism, a genome-wide library of *Escherichia coli* clones have been developed, where each clone expresses a dsRNA for an individual gene in *C. elegans*. Feeding *E. coli* expressing dsRNA for a specific gene causes an inhibition of that gene in an otherwise wild-type organism.

Most often, the RNAi technology produces a "knockdown" of the expression of a given gene and does not completely inactivate expression. Therefore, it cannot be routinely used to study the null phenotype of a "knockout" of that gene. Nevertheless, the approach of using RNAi is proving to be tremendously useful as a tool for rapidly downregulating specific genes to study their function in various organisms. This has been particularly the case in *C. elegans*, where the knockdown of any gene can be quickly tested by feeding the appropriate clone of *E. coli* to the worms.

3. Naturally occurring sequence variations to study gene function

Unlike experimental mutagenesis that involves the generation of new mutations within genes, it is also possible to study the function of genes by exploiting the naturally occurring sequence variations that arise from spontaneous mutations in the germline of organisms (*see* Article 40, **Farm animals**, Volume 3). These spontaneous mutations create the genetic diversity that causes the different biological and disease-specific traits within individuals in a population.

The genes impacted by spontaneous mutations can be identified through a process called positional cloning. Positional cloning involves scanning the DNA of individuals in a test population with molecular markers that are capable of differentiating the parental alleles at hundreds of loci throughout the genome. Analysis of the data will reveal the region of the genome, called the critical region, that cosegregates with the mutant phenotype. Genes within the critical region are evaluated, and eventually the single gene that contains a sequence variant that

causes the mutant phenotype is identified. This process of positional cloning has become commonplace in the genetics community in recent years and was greatly facilitated by having access to the genome sequence and knowledge of the position of essentially all genes. It is the only way to conduct molecular genetics experiments in humans.

Compared to experiments in humans, however, studying spontaneous mutations is enhanced in most model organisms by the availability of genetically pure inbred lines. Inbred lines are those that are produced by sequential brother–sister mating such that all of the offspring within that line are essentially genetically identical. Examples of inbred lines are C57BL/6 J in mice, Sprague–Dawley in rats, and C32 and SJD in zebrafish. Other types of special genetic lines in several model organisms are based on shuffling genome segments from inbred lines. Recombinant inbred, or RI, lines are stable lines that are generated by crossing different inbred lines followed by brother–sister mating for many generations to stabilize the genome. Each RI line has a variable-sized chromosomal segment throughout the genome from each of the parental lines. Congenic lines are those that have a single chromosomal region of varying length from one inbred line, with the rest of the genome being derived from a second inbred line. Consomic lines are those that harbor one full chromosome from one inbred line with all of the other chromosomes being from a second inbred background.

Each inbred line has a different assortment of alleles that are fixed in the genome. Not every gene is different between each of these lines, but the various inbred strains each contain allelic differences within genes that often result in dramatically different phenotypes. Unlike simple Mendelian traits that are associated with a mutation in a single gene, most of the phenotypic differences between inbred lines arise from the complex interactions of allelic variations within multiple genes. These are referred to as complex traits. The individual loci that contribute to a complex trait are called complex trait loci, or QTLs (*see* Article 38, **Mouse models**, Volume 3). Examples of complex traits are blood pressure, atherosclerosis, osteoporosis, diabetes, and obesity.

There are considerable efforts under way to discover the allelic variants with the genes that underlie complex traits. These most often involve controlled breeding experiments between different inbred lines that exhibit extremes for a given phenotype, such as high and low blood pressure, although the direct analysis of RI, consomic, and congenic lines is also being used to study QTLs and complex traits. While it still remains a challenge to identify the allelic variants within specific genes that contribute to complex traits, the genome resources that are now available from the genome project are now making it possible to begin to characterize QTLs at the molecular level (*see* Article 38, **Mouse models**, Volume 3).

4. Genetics and model organisms

Each of the six model organisms described here has its own advantages and disadvantages. The mouse is one of the most versatile of model organisms for genetics experiments (*see* Article 38, **Mouse models**, Volume 3). In addition to the conservation of genome content and organization with that of the human genome, the mouse

has an anatomy and physiology that, in many cases, resembles that in humans. It has a rich history of genetic analysis, and is the focus of considerable current work in experimental genetics. There are many resources that maintain spontaneous, insertional, transgenic, chemical- and radiation-induced mutants, and there are inbred, congenic, consomic, and recombinant inbred lines available that take advantage of normal sequence variations in mice. Most notably, other than yeast, the laboratory mouse is the only organism where it is possible to efficiently alter gene expression by generating targeted mutations by homologous recombination.

There are some experiments that require a larger rodent than the mouse. In these cases, the rat is often used (*see* Article 39, **The rat as a model physiological system**, Volume 3). Like the mouse, there are spontaneous mutants, inbred lines, and congenic lines available, and it is possible to create transgenic lines of rats. There are protocols available for conducting mutagenesis experiments with chemicals such as ENU. However, the size of the rat resource does not match that of the mouse, and it is not possible to produce targeted mutations, by homologous recombination.

There are also certain types of experiments that are uniquely well suited for other model organisms. The relatively simple genome, rapid generation time, ability to generate and maintain large numbers of offspring, accessibility to the developing embryo, efficient strategies for chemical and mobile genetic element experimental mutagenesis, and extensive genetics resources make *Drosophila* the organism of choice for many experiments for studying gene function (*see* Article 42, **Systematic mutagenesis of nonmammalian model species**, Volume 3). The fact that the early embryo is transparent makes *Danio* a perfect model for studying the earliest stages of embryonic development, and *Caenorhabditis* has numerous advantages for experiments in developmental biology because there are less than 1000 cells in the entire adult organism, and the fate of each cell has been mapped (*see* Article 42, **Systematic mutagenesis of nonmammalian model species**, Volume 3). Finally, for other experiments that involve cellular processes, *Saccharomyces* may prove to be the organism of choice (*see* Article 43, **Functional genomics in *Saccharomyces cerevisiae***, Volume 3).

5. Databases as research tools to study gene function

The nature of biological research has changed with the genome project. New tools to collect large complex data sets are now available, and teamwork involving multiple groups of investigators at different institutions is becoming the norm. Databases now serve as centralized electronic repositories for data collected around the world. The components are now in place to support a new paradigm for conducting biological research that embraces the complexity associated with most biological systems. This new approach for biological research is referred to as "integrative biology", where data sets from multiple organisms are collected and mined computationally to reveal patterns in the data that would not have emerged if each data set was analyzed in isolation from the others. Ultimately, access to these new informatics tools should help the biological community understand how whole sets of genes function in complex biological systems.

One key component to integrative biology is to develop databases that serve as data integration hubs for each of the various model organisms. Most of the model organisms that are commonly used in biomedical research have a model organism-specific community database to support data integration and manual curation. The Mouse Genome Informatics (MGI; **http://www.informatics.jax.org**), for example, is a widely the recognized community database for the laboratory mouse. MGI integrates genetic and genomic data for the mouse in order to service its mission to facilitate the use of the mouse as a model system for understanding human biology and disease processes. The MGI database provides extensive information about mouse genes, sequences, alleles, mutant phenotypes, QTLs, strain polymorphisms, gene and protein function, developmental gene expression patterns, and curated mammalian homology (especially for rat and human) data. Data pertaining to all types of mouse lines described in this report are available to the research community (e.g., new ENU mutants, transgenic, targeted mutations, etc.) and are accessible from the MGI database. MGI is also a platform for computational assessment of integrated biological data with the goal of identifying candidate genes associated with complex phenotypes. Similar integrated databases for yeast (**http://www.yeastgenome.org/**), the fly (**http://flybase.bio.indiana.edu/**), the worm (**http://www.wormbase.org/**), zebra fish (**http://zfin.org**), and the rat (**http://rgd.mcw.edu/**) are also available. Multiple integrated electronic resources are available for accessing genetic and genomic data for humans (**http://www.ncbi.nlm.nih.gov/genome/guide/human/**; **http://www.ensembl.org**; **http://genome.ucsc.edu**).

In addition to building information systems that focus on the integration of diverse data for a single organism, it is also critical to the advancement of biomedical research to be able to compare functional genomic data across organisms. Developing standards that support this comparative genomics approach to functional genomics is currently a major focus of activities in the bioinformatics community and one such effort is being led by the Gene Ontology (GO) Consortium (**http://www.geneontology.org**). This GO Consortium is developing controlled vocabularies of terms related to the molecular function, biological process, and cellular location of gene products. The GO group both develops the terms and their definitions and then annotates genes and gene products using the terms. Consistent use of biological terms across different organisms means that researchers can retrieve data for a single organism or for multiple organisms accurately and consistently. Being able to compare data across species makes it possible to use and play to the strengths of all the different model organisms to study the function of genes.

6. Summary

Studying the function of genes is a multidimensional process that involves many organisms and a large variety of experimental approaches. No single organism is best suited for all experiments, and no single experimental strategy is appropriate for all genes. In the end, integrated electronic resources with data collected from all genes in yeast, flies, worms, mice, zebra fish, rats, and human will best serve the needs of the biomedical research community to study gene function.

Specialist Review

Mouse models

Michelle E. Goldsworthy and Roger D. Cox
Medical Research Council Harwell, Harwell, UK

1. Introduction

1.1. Why use the mouse as a model system?

The mouse has very well-defined genetics, with genetically homogenous inbred strains and a completed genome sequence. In addition, mice have a short breeding time that allows easy generation of sufficient numbers of individuals for an experiment, defined housing conditions including diet and health status, well-developed and still evolving phenotyping technologies, and a broad range of genetic manipulation tools. Figure 1 illustrates these advantages as compared to heterogeneous human populations.

1.2. What can the mouse really model?

We would like the mouse to model human disease but we obviously know that there are differences between these two species, which means that we must be realistic in our expectations. Among the many similarities are a similar sized genome and number of genes and broadly similar physiology. There are obvious differences in some aspects of basic biochemistry (mice have high HDL-cholesterol, for example), life span, and size. A mouse with mutations in the same genes that are mutated in human may not always fully recapitulate the human disease but it is important to remember that the differences may be informative and the similarities sufficient to allow investigation of some of the mechanisms involved that might otherwise be impossible. Thus, the mouse may serve as a model at different levels from fully representing a human disease and its genetics at one extreme to yielding insights into particular molecules or molecular interactions that form part of a disease process, or just as relevantly normal biology, conserved in humans at the other extreme. At this latter extreme, other lower organisms (for example, *Caenorhabditis elegans*) may also serve. Figure 1 illustrates some of these concepts. Through the mapping and cloning of genes underlying a phenotype in mouse, such as for example obesity, a whole new field may be born that gives fundamental insight into basic mechanisms, such as the control of food intake and metabolism. While these discoveries may not have identified the precise genetic factors contributing

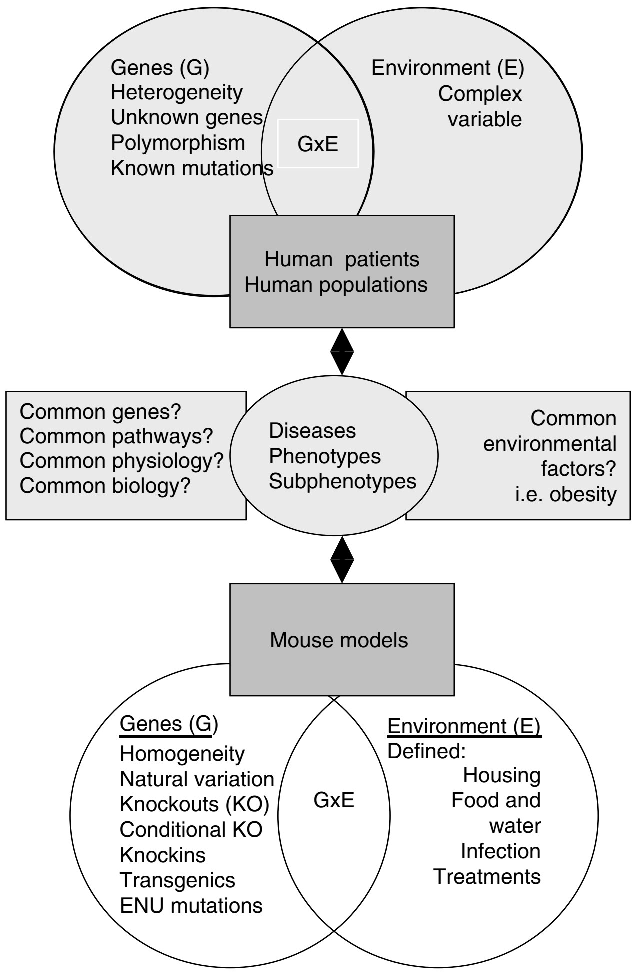

Figure 1 The expression of a phenotype or disease depends on the interaction of genes and environment. In the mouse, these factors can be well defined but their use as models for human disease analysis depends on there being at least some similarity in the genes, pathways, physiology, and biology of the process being studied – which is often true

to common human obesity disorders, they have at least described some of the fundamental pathways that are common to both species. Finally, in pathways that may be associated with human disease, where we know some of the genes that are involved in the mouse, it has been possible to investigate the basic processes that also operate in human but can only easily be modeled in another species. Using the example of obesity and type 2 diabetes, we will further elaborate on some of these points.

In type 2 diabetes, one finds both impairment of insulin secretion and insulin resistance (for a recent review, see Ashcroft and Rorsman, 2004). Insulin resistance is characterized by the impaired ability of insulin to inhibit hepatic glucose production and to stimulate glucose uptake by skeletal muscle. Insulin also fails to

suppress lipolysis in adipose tissue, which in turn increases circulating nonesterified fatty acid (NEFA) concentrations that stimulate gluconeogenesis, triglyceride synthesis, and glucose production in the liver. Insulin resistance generally increases in parallel with increasing body-fat mass with increased levels of obesity being largely responsible for the rise in prevalence of type 2 diabetes in the developed world. Although no mouse model of type 2 diabetes to date faithfully mimics all aspects of type 2 diabetes and obesity in humans, single gene spontaneous and induced mutations, transgenic mice and genetic differences between inbred mouse strains (QTLs) have all added to the understanding of the underlying metabolic pathways and disease processes some of which will be discussed in this review.

2. Spontaneous single-gene mutations

Obesity is a complex trait influenced by genetic factors in addition to age, gender, diet, and exercise. Body weight and appetite are mainly regulated by neuropeptides released from the hypothalamus in response to signals from fat, muscle, the liver, and gastrointestinal tract, and physiologically obesity can be the result of changes in either appetite, nutrient turnover, or thermogenesis. Disruption in energy balance homeostasis can also cause hyperleptinemia and hyperinsulinemia with obesity itself perhaps the greatest risk factor for the development of type 2 diabetes, coronary heart disease, and other metabolic disorders.

A number of spontaneous single-gene mutations result in obesity in the mouse and the mapping and cloning of these kick started this field, resulting in fundamental and novel discoveries. These include *obese* (ob) and *diabetic* (db) mouse models. Obesity in these models results from mutations in the hormone leptin and its receptor respectively. Leptin is a soluble hormone secreted from adipocytes that signal through the pro-opiomelanocortin (POMC) and neuropeptide Y (NPY) neurones in the hypothalamic arcuate nucleus (ARC), which normally controls feeding. POMC neurones also respond to a variety of other factors including dopamine, gonodal steroids, glucose, and insulin (Baskin *et al*., 1999), which would imply a broader role for these neurons in communicating peripheral information regarding energy homeostasis to centers controlling feeding and metabolism. Lack of biologically active leptin or leptin receptor effectively prevents normal signaling of energy stores by the adipose tissue to the hypothalamus, resulting in hyperphagia, decreased energy expenditure, and the accumulation of excess fat. The replacement of exogenous leptin in ob/ob and wild-type mice results in weight loss, decreased food intake, and increased physical activity, whereas as expected db/db mice are unaffected. Both ob/ob and db/db mouse strains exhibit in addition to obesity hyperinsulinemia, insulin resistance, and ultimately hyperglycemia becoming severely diabetic. Additionally, the interruption of leptin or α-melanocyte stimulating hormone (α-MSH) signaling in the hypothalamus is thought to be the primary cause of obesity in agouti (A^y) and Mc4r null mice.

The *tubby* stain of obese mice arose as a spontaneous mutation in the Jackson mouse colony (Coleman, 1990) and phenotypically is characterized by maturity-onset obesity accompanied by retinal and cochlear degeneration (Ohlemiller, 1997). The development of obesity in tubby mice is relatively mild and resembles weight

gain in humans more closely than that observed in *obese* (ob) and *diabetes* (db) mouse strains and resembles the phenotype observed in Ushers, Bardet-Biedl, and Alstrom syndromes in humans. Positional cloning of the *tub* gene identified it is a member of a novel gene family and appears to be specifically expressed within the nervous system, in the key hypothalamic nuclei that have been implicated in the central control of energy homeostasis (Kapeller, 1999). $Tub^{tmlRok-}$ knockout (KO) mice are phenotypically indistinguishable from tubby mice, indicating that the tubby phenotype is due to loss of function (Stubdal, 2000). *Tub* has been shown to be tyrosine phosphorylated in response to insulin and insulin growth factor-1. In vitro *tub* is phosphorylated by purified insulin receptor kinase, Abl, and JAK 2 but not by epidermal growth factor receptor and Src kinases, data that suggests that *tub* may function as an adaptor protein linking the insulin receptor and possibly other protein tyrosine kinases to SH2-containing proteins (Kapeller, 1999).

Agouti (A^y), a classic coat color mutant encoding the agouti signaling peptide is an antagonist of melanocortin 4-receptor (Mc4r) signaling; obesity in these mice is the result of aberrant antagonism of the hypothalamic Mc4r. The targeted disruption of other melanocortin receptors expressed in the CNS, for example $Mc4r^{tmlDhu}$ knockout mice or their peptides have confirmed this pathway as essential for the control of energy homeostasis (Huszar, 1997). $Mc4r^{tmlDhu}$ mice fed a moderately high fat diet were utilized in investigating the relative importance of Mc4r compared to leptin in control of food intake, food restriction and response to increased fat, energy expenditure, and activity (Butler, 2001). In order to investigate adaption to food restriction, $Mc4r^{tmlDhu-}$, $Mc3r^{tmlCone}$, $lep^{ob}/\ lep^{ob}$ and wild-type mice were fed a restricted diet for 96 h followed by reintroduction of ad libitum feeding. Absolute weight loss was similar across all groups and the kinetics of return to prediet weight was similar; this would imply therefore that neither Mc4r or Mc3r seem necessary for the sensing of nutritional defects. Feeding in response to diet was also studied, all four groups were swapped from a low to moderate fat diet, food intake and weight were increased in $Mc4r^{tmlDhu}$ mice but not in $Mc3r^{tmlCone}$ or in wild-type controls. No increase in weight or consumption was observed in $lep^{ob}/\ lep^{ob}$ mice, suggesting that Mc4r but not Mc3r might have a leptin-independent effect on food intake. Additionally, feed efficiency, that is weight gain per kilocalorie ingested was markedly increased in $Mc4r^{tmlDhu}$ mice but not in $lep^{ob}/\ lep^{ob}$ or in wild-type controls, which would suggest a specific interaction between Mc4r and fat content in the diet. Energy expenditure and increase in activity in response to moderate fat diet were also studied. Energy expenditure was measured using indirect calorimetry; mice were fed a low fat diet for 3 days followed by moderate fat diet for 3 days. Basal and total O_2 consumption during low fat chow consumption was low in ob/ob compared with wild-type and $Mc4r^{tmlDhu}$ mice. Following the switch to moderate fat chow, wild-type and ob/ob mice responded by increasing basal and total oxygen consumption with no response observed in $Mc4r^{tmlDhu}$ null mice. Activity measured by wheel running was also increased following moderate fat chow in wild type compared to $Mc4r^{tmlDhu}$ null mice. Therefore, Mc4r seems to be needed for regulation of activity-based energy expenditure in response to diet as well as being an important factor in the stimulation of diet induced thermogenesis. This study shows some of the advantages of using the mouse specifically to manipulate molecules of interest

and control environmental factors as well as being able to apply sophisticated phenotyping techniques to sufficient numbers of individuals to generate statistically valid results.

The obesity story illustrates the power of the mouse to yield insights into the fundamental mechanisms of control of energy homeostasis. The mouse as a model system is key to the understanding of this field. These various obesity mutants are not per se models for human obesity. For example, relatively few patients have mutations in leptin or its receptor, but they are models for investigating these highly conserved pathways – research that may lead ultimately to new therapeutic interventions (Flier, 2004).

3. Tissue-specific knockouts

In processes where genes are known to be involved, the mouse provides an extensive toolkit to investigate their action in more detail?. For example, the relative contribution of components of insulin signaling pathways, glucose uptake and insulin resistance have been studied via the generation of global or tissue-specific knockouts. A global homozygous knockout of the insulin receptor in mouse leads to fatal ketoacidosis in neonates; however, heterozygotes exhibit mild hyperglycemia with a corresponding hyperinsulinemia with some 10% of adult mice eventually developing diabetes dependent on background strain (Accili *et al*., 1996). A number of tissue-specific insulin receptor knockouts were generated using the Cre/loxP system and they have elucidated some of the complex interactions between various tissues during the development of impaired glucose tolerance and type 2 diabetes (summarized in Table 1). Surprisingly, muscle specific insulin receptor knockout (MIRKO) mice appeared to have normal glucose tolerance although insulin-stimulated muscle glucose uptake and glycogen synthesis were severely impaired accompanied by an increase in insulin-stimulated glucose transport in fat (Bruning, 1998; Kim *et al*., 2000). In addition, MIRKO mice have elevated fat deposits, serum triglycerides, and free fatty acid levels; thus, insulin resistance in muscle leads to dislipidemia and obesity but not to diabetes. Liver-specific insulin receptor knockout (LIRKO) in contrast exhibited severe insulin resistance, glucose intolerance and a failure of insulin to suppress hepatic glucose production (Michael *et al*., 2000). Mice additionally had marked hyperinsulinemia and an almost sixfold increase in β-cell mass. β-cell insulin receptor knockout βIRKO) mice lack glucose induced first phase insulin release and develop glucose intolerance with age (Kulkarni *et al*., 1999).

Global knockouts of signaling molecules downstream of the insulin receptor such as Irs1, Irs2, and Irs3 have also been studied. Irs1 is a principal substrate for insulin and insulin-like growth factor (IgF1) receptors. After tyrosine phosphorylation at several sites, Irs1 binds to and activates phosphatidylinositol-3-kinase (PI3K). Mice homozygous for Irs1 knockouts as expected showed no Irs1 phosphorylation or PI3K activity and a 50% reduction in intrauterine growth, impaired glucose tolerance, and a decrease in insulin-stimulated glucose uptake (Araki *et al*., 1994). Irs2 appears to act as an alternative substrate of the insulin receptor, and in Irs1 knockout mice, Irs2 substitutes for Irs1 leading to a marked increase in β-cell

Table 1 A summary of the many tissue and gene specific mouse knockout models of type 2 diabetes

Gene-/tissue-specific knockouts	Description of phenotype	References
$IR^{-/-}$	Diabetic ketoacidosis, early postnatal death	Joshi *et al*., (1996); Accili *et al*. (1996)
MIRKO	Elevated fat mass, serum triglycerides, and free fatty acids. Normal glucose, glucose and insulin tolerance	Bruning *et al*. (1998); Kim *et al*. (2000)
LIRKO	Severe glucose intolerance, failure to suppress glucose production, insulin resistance, and hyperinsulinemia	Michael *et al*. (2000)
βIRKO	Severe loss of insulin secretion in response to insulin, progressive impairment of glucose tolerance	Kulkarni *et al*. (1999)
NIRKO	Normal brain development and survival, diet sensitive obesity, and increased insulin and triglyceride levels	Bruning *et al*. (2000)
IRS-$1^{-/-}$	Growth retardation, mild insulin resistance, β-cell hyperplasia, hyperinsulinemia	Araki *et al*. (1994)
IRS-$2^{-/-}$	Severe insulin resistance, reduced β-cell mass, early diabetes	Withers *et al*. (1998); Kubota *et al*. (2000)
$IR^{+/-}$ IRS-$1^{+/-}$	Severe insulin resistance in muscle and liver, β-cell hyperplasia	Kido *et al*. (2000)
$IR^{+/-}$ IRS-$2^{+/-}$	Severe insulin resistance in liver but mild insulin resistance in muscle, moderate β-cell hyperplasia	Kido *et al*. (2000)
$IR^{+/-}$ IRS-$1^{+/-}$ IRS-$2^{+/-}$	Severe insulin resistance in liver and muscle, marked β-cell hyperplasia	Kido *et al*. (2000)
$GLUT4^{-/-}$	Moderate insulin resistance, glucose intolerance, and decreased adipocyte mass	Katz *et al*. (1995)
$GLUT4^{-/+}$	Insulin resistance, diabetes, hypertension	Stenbit *et al*. (1997)
MG4KO	Insulin resistance, glucose intolerance	Zisman *et al*. (2000)
FG4KO	Insulin resistance in muscle and liver, glucose intolerance, hyperinsulinemia	Abel *et al*. (2001)
$GLUT2^{-/-}$	Glucose intolerance, impaired insulin secretion, diabetes, and early death	Guillam *et al*. (1997)
$GK^{-/-}$ or β-cell $GK^{-/-}$	Diabetic ketoacidosis, early postnatal death	Grupe *et al*. (1995); Terauchi *et al*. (1995)
$GK^{-/+}$ or β-cell $GK^{+/-}$	Impaired insulin secretion, mild diabetes	Grupe *et al*. (1995); Terauchi *et al*. (1995)
Liver $GK^{-/-}$	Mild hyperglycemia	Postic *et al*. (1999)

mass resulting in increased insulin secretion. In contrast, knockout of Irs2 leads to hyperglycemia and insulin resistance; this is accompanied by a twofold reduction in β-cell mass with insulin secretion in response to insulin that decreased as hyperglycemia became more severe (Withers *et al*., 1998; Kubota *et al*., 2000) and the animals developed diabetes by 10 weeks of age. Differences in severity of disease in different knockout models have been attributed to modifiers in the

background strain (Terauchi *et al*., 2003). Irs3 (an isoform restricted to adipose tissue) null mice (Liu, 1999) in contrast showed normal body weight and normal blood glucose and insulin levels.

One physiological effect of insulin is stimulation of glucose uptake, with increased glucose transport in skeletal muscle and adipose tissue required for normalizing postprandial hyperglycemia. One result of insulin signaling leading to glucose uptake is translocation of GLUT-4 (the glucose transporter expressed in skeletal muscle, heart, and adipocytes) to the plasma membrane and uptake of circulating glucose (for a review of the insulin signaling pathway, see Bevan, 2001). GLUT-4 knockout mice, however, do not develop diabetes, exhibiting only moderate insulin resistance and impaired glucose tolerance (Katz *et al*., 1995; Stenbit *et al*., 1997). The loss of GLUT-4 however did result in growth retardation, reduced fat tissue, cardiac hypertrophy, and a shortened lifespan. Like the insulin receptor, tissue-specific knockouts of GLUT-4 in muscle and fat have been created. Muscle-specific knockouts (MG4KO) mice developed severe insulin resistance and glucose intolerance. Unexpectedly, fat-specific knockouts (FG4KO) showed, as well as impaired insulin-stimulated glucose uptake in adipocytes, insulin resistance in both muscle and liver (Abel *et al*., 2001). The mechanism by which this apparent fat cell defect alters insulin action in muscle and liver remains unclear but it is consistent with the view of the adipocyte as an endocrine cell (see Flier, 2004 for a recent review). Knockout studies indicate the glucose transporter 2 (GLUT2 Slc2a2) along with glucokinase is involved in the highly regulated process of insulin secretion by the β-cell. GLUT-2 (Slc2a2) deficient mice developed hyperglycemia and hypoinsulinemia, leading to severe diabetes and death within the first 3 weeks following birth (Guillam *et al*., 1997). $Slc2a2^{tmlThor}$ mice exhibited severely impaired glucose tolerance and isolated islet studies showed impaired glucose stimulated insulin secretion. $Slc2a2^{tmlThor}$ mice could be rescued by transgenic reconstitution of Slc2a2 expression in the β-cells alone (Thorens, 2000).

These examples illustrate the potential of the mouse to model specific deficiencies of known molecules, which when combined with tissue specific elimination, reveals some unexpected tissue interactions. The obvious limitation of null mutations is that they may mask some important interactions if the gene involved is essential for some earlier step such as embryogenesis.

4. Multigenic models

A panel of mutations affecting different aspects of a pathway or interacting system can relatively easily be combined by breeding in the mouse to generate a multigenic model with the purpose of investigating gene and pathway interactions and potentially generating more representative models of human disease. There are, for example, mutants that reduce HDL-cholesterol in the mouse that could be combined with other risk factor genes for cardiovascular disease.

In the diabetes field, knockout strains of mice have been combined in order to produce polygenic models of diabetes. Mutant mice heterozygous null for both the insulin receptor (Insr) and insulin receptor substrate 1 (Irs1) genes developed severe insulin resistance in muscle and liver with 40% of mice becoming overtly diabetic

by 6 months of age in contrast to each mutation alone (Bruning, 1997). In this model, insulin resistance was accompanied by compensatory β-cell hyperplasia and hyperinsulinemia in an effort to overcome insulin resistance. Doubly heterozygous Irs1 and Irs2 knockout mice developed insulin resistance in the liver with less pronounced β-cell hyperplasia and diabetes (Kido *et al*., 2000), while triple heterozygous mice for Insr, Irs1, and Irs2 developed severe early onset diabetes, characterized by insulin resistance in both muscle and liver accompanied by a compensatory increase in β-cell mass. Double knockouts of Irs1$^{-/-}$ and Irs3$^{-/-}$ unlike Irs1$^{-/-}$ alone were characterized by marked hyperglycemia (Laustsen, 2002) and thus would appear to compensate for each other's functions, no such compensation, however, was observed in Irs2$^{-/-}$ Irs$^{-/-}$ mice (Terauchi *et al*., 2003). In order to further characterize the interaction between Irs2 and β-cell function, Withers (1999) crossed insulin-like growth factor-1 receptor (Igf1r) and Irs2 knockout mice. Igf1r null mice die soon after birth, have elevated blood glucose levels and histological analysis showed failure of α- and β-cell of the pancreas to organize into mature islets, suggesting that like Irs2, Igf1r had a role in the development of normal function islets. Similar to Irs2, null animals Igf1r$^{+/-}$ Irs$^{-/-}$ animals showed glucose intolerance, polyuria, and weight loss. The reduction in β-cell area observed was more pronounced than that observed in Irs2 null animals alone suggesting that Igf1r/Irs2 signaling pathway is critical for β-cell proliferation and function. Tissue-specific knockouts have also been used to reconstitute a polygenic model of type 2 diabetes. Mice homozygous null for the IRS-1 gene but heterozygous for a β-cell-specific glucokinase knockout, which individually did not give rise to an overt diabetic phenotype, developed hyperglycemia, β-cell hyperplasia, and eventually diabetes with age (Terauchi *et al*., 1997).

5. Mutagenesis

Knockout models of type 2 diabetes and obesity, although providing information on disease processes, do not mimic human disease, which is multigenic in nature and likely arises from common sequence variants rather than from null mutations. Disease in humans is predominately caused by the additive effects of multiple genes and environmental influences. Random mutagenesis using the point mutation *N*-ethyl-*N*-nitrosourea (ENU) is well established in the mouse, and large-scale phenotype driven ENU screens are increasingly being used for the systematic analysis of gene function throughout the mouse genome. Point mutations induced by ENU mutagenesis can lead to both hypomorph, hypermorph, gain of function, and dominant negative mutants, which may be more relevant than null alleles in human disease. Mutagenesis screens to date have utilized free-fed blood biochemistry in biochemical screens to identify mutants with disruption in glucose homeostasis (Nolan, 2000; Hough, 2002). While free-fed blood biochemistry is a quick assay, it may bias the mutations identified to autosomal dominant models of MODY (Toye, 2004). Adopting additional phenotyping protocols such as an intraperitoneal glucose tolerance test (IPGTT) or insulin suppression tests will identify more subtle insulin-resistant and glucose-intolerant phenotypes. Further sensitizing the screen utilizing existing knockout models, for instance, those predisposed to insulin resistance

without developing diabetes, will identify interacting genes, which alone would not have been identified in a standard dominant or recessive screen. The knockout models can be chosen to identify interacting genes in specific aspects of diabetes, for instance, an insulin receptor knockout and the insulin signaling pathway. Such approaches may identify novel genes not considered to be diabetes candidate genes. Furthermore, environment conditions can also be manipulated such as feeding a high-fat diet in order to exacerbate disease or identify susceptibility loci.

6. Quantitative trait loci (QTL) studies

Numerous quantitative trait loci (QTL) studies have been carried out in mouse taking advantage of an array of differing inbred mouse strains for a wide variety of diabetes related phenotypes including, glucose tolerance, blood plasma glucose, and insulin concentrations, body weight, lipid concentrations, and hypertension. To date, some 75 QTLs for obesity and 85 QTLs for body weight have been identified in various mouse lines and map to every chromosome except Y (for recent reviews, see Brockmann and Bevova, 2002; Cox and Brown, 2003). Few genes to date have been identified; however, the availability of complete genome sequence of the mouse is likely to speed up the search for candidate genes in QTL loci. Advances in the QTL field are likely to center around the use of more sophisticated breeding schemes that take advantage of the wide and significant differences between multiple inbred strains such as the use of heterogeneous stocks (Hss) (Mott, 2000).

7. RNA interference (RNAi)

Although not yet feasible in mouse, large-scale RNAi screens have been successfully applied to fat regulation in simpler organisms such as *C. elegans*. Ashrafi *et al*. (2003) have screened the expression of some 16 757 worm genes and assayed for modulations in fat storage. Utilizing a double-stranded RNAi bacterial library that contains some 86% of the 19 000 *C. elegans* genes expressed in *Escherichia coli*, which was fed to the worms as food. Additionally, a dye, Nile red, was also fed to the worms, which enables the visualization of fat storage droplets in living worms. They identified 305 gene inactivations that caused reduced body fat and 112 genes that caused increased fat storage. Although a number of genes identified in the screen were already known to have a key role in mammalian fat or lipid metabolism, over 50% of the fat regulatory genes identified in the study have mammalian homologs that have not been previously implicated in the regulation of fat storage and may present interesting genes for further study in rodent models.

8. Concluding remarks

The mouse has a proven track record as a model organism that has made significant contribution to the understanding of disease and biology relevant to the human.

It is not the only model organism by any means but for the study of human disease, it is perhaps one of the most widely used. We have illustrated the multiple approaches that can be brought to bear to model human disease using as examples the study of type 2 diabetes and obesity in the mouse. Spontaneous mutations and knockouts have given insight into the relative contributions of differing genes in the regulation of glucose homeostasis, insulin resistance β-cell function, and adiposity. Tissue-specific knockouts have gone some way into dissecting the relative contributions of multiple tissues and organs to disease progression. Combinations of different mutants, which individually would not produce disease have resulted in polygenic models of type 2 diabetes. Sensitized ENU mutagenesis screens may yield additional novel diabetes genes. The mouse has only been one of the approaches available to us to investigate human disease, but together with studies in human populations, other model organisms and in vitro systems, it has opened unprecedented opportunities in this new century to really tackle the problem of common human disease.

Specialist Review

The rat as a model physiological system

Dominique Gauguier
University of Oxford, Oxford, UK

1. Introduction

Much of our current understanding of integrative physiology is based on studies in the laboratory rat, and the body of physiological and pathophysiological data, as well as toxicological and pharmacological data, that are available for the rat is unparalleled in other species (Jacob and Kwitek, 2001). The rat has been the favored model for physiologists in various fields of biomedical research because of its large size, which facilitates invasive and repeated experimental interventions that remain technically difficult or impossible to apply in mice. It provides a broad range of unique and thoroughly studied models of common and prevalent human complex disorders, including type 1 and type 2 diabetes mellitus, essential hypertension, stroke, obesity and renal, neurological and autoimmune disorders. This chapter focuses on the description of rat models and tools used in the genetic study of quantitative traits (*see* Article 58, **Concept of complex trait genetics**, Volume 2), which is a particularly active field of research in the rat.

2. Rat models commonly used in genetic studies

Over 230 different inbred rat strains have been derived since the inbreeding of the first rat strain in 1909 – the same year that inbreeding of the first mouse strain began. Although genetic research has focused on well-characterized rat models of Mendelian and polygenic diseases (Table 1), an important proportion of inbred rat strains, showing potentially considerable genetic diversity, are still underutilized in physiological and genetics studies.

In contrast to mouse models (*see* Article 38, **Mouse models**, Volume 3), there are few rat models of disease traits spontaneously occurring as the consequence of a single gene mutation (see Section 7.1). In the absence of models spontaneously mirroring the etiology and pathogenesis of the most frequent and prevalent human diseases (e.g., diabetes mellitus, hypertension), a process of repeated breeding of increasingly affected animals isolated from an outbred stock has been used to produce rat strains exhibiting specific disease phenotypes (Table 1). This procedure

Table 1 Pathophysiological characteristics of major inbred rat strains used in QTL mapping experiments

Strain	Description	Original stock	Selection criterion[a] or main disease features[b]
ACI	August x Copenhagen Irish	–	Resistance to arthritis[b]
AS	Albino Surgery	Wistar	High blood pressure[a]
BBDP	Biobreeding diabetes prone	Wistar	Lymphopenia[b], type 1 diabetes mellitus[b]
BN	Brown Norway	–	High IgE[b], aortic IEL lesions[b], spike-wave discharges[b], resistance to mammary and liver cancers[b], resistance to arthritis[b]
CDS	Cohen diabetic sensitive	Unknown	Glucose intolerance on high-sucrose low-copper diet[a]
COP	Copenhagen	–	Resistance to mammary and liver cancers[b]
DA	Dark Agouti	–	Experimentally induced arthritis and autoimmune encephalomyelitis[b]
DRH	Donryu-RH	Donryu	Resistance to liver cancer[a]
E3	–	–	Resistance to pristane-induced arthritis[b]
FHH	Fawn Hooded	German-brown x White Lashley	High blood pressure[a]
F344	Fisher	–	Cancer susceptibility[b], spike-wave discharges[b], resistance to arthritis[b]
GAERS	Genetic absence epilepsy	Wistar	Absence seizures and spike-wave discharges[a] Rat from Strasbourg
GH	Genetically hypertensive	Wistar	High blood pressure[a]
GK	Goto-Kakizaki	Wistar	Glucose intolerance[a]
HTG	Hereditary hypertriglyceridemic	Wistar	Elevated plasma triglycerides[a]
KDP	Komeda diabetes prone	LETL	Type 1 diabetes mellitus[b]
LEW	Lewis	–	Experimental autoimmune encephalomyelitis[b]
LH	Lyon hypertensive	Sprague-Dawley	High blood pressure[a]
LN	Lyon normotensive	Sprague-Dawley	Normal blood pressure[a]
MHS	Milan hypertensive	Wistar	High blood pressure[a]
MNS	Milan normotensive	Wistar	Normal blood pressure[a]
MWF	Munich Wistar Fromter	Wistar	High number of superficial glomeruli[a], proteinuria[b], glomerulosclerosis[b], hypertensionb
OLETF	Otsuka Long Evans Fatty	Long Evans	Glucose intolerance[a] and obesity[b]
PKD(*Cy*)	–	Sprague-Dawley	Polycystic kidney disease[b]
RHA/Verh	Roman high avoidance	Wistar	Conditioned-avoidance response[a]
RLA/Verh	Roman low avoidance	Wistar	Conditioned-avoidance response[a]
SBH	Sabra hypertensive	Unknown	High blood pressure in response to unilateral nephrectomy[a]
SHR	Spontaneously hypertensive	Wistar	High blood pressure[a]
SHRSP	SHR Stroke prone	Wistar (SHR)	Stroke susceptibility[a]
SS	Salt sensitive	Sprague-Dawley	Salt induced high blood pressure[a]
SR	Salt resistant	Sprague-Dawley	Low blood pressure on high salt diet[a]
SDT	Spontaneously Diabetic Torii	Sprague-Dawley	Hyperglycemia and glucosuria[a]
WAG/Rij	Wistar Albino Glaxo	Wistar	Absence seizures and spike-wave discharges[a]
WBN/Kob	Wistar Bonn/Kobori	Wistar	Chronic pancreatitis and diabetes mellitus[b]
WF	Wistar Furth	Wistar	Susceptibility to DMBA-induced mammary cancer[b]
WKHA	Wistar Hyperactive	Wistar (SHR/WKY)	Normal blood pressure and hyperactivity[a]
WKY	Wistar Kyoto	Wistar	Normal blood pressure[a], resistance to mammary cancers[b]

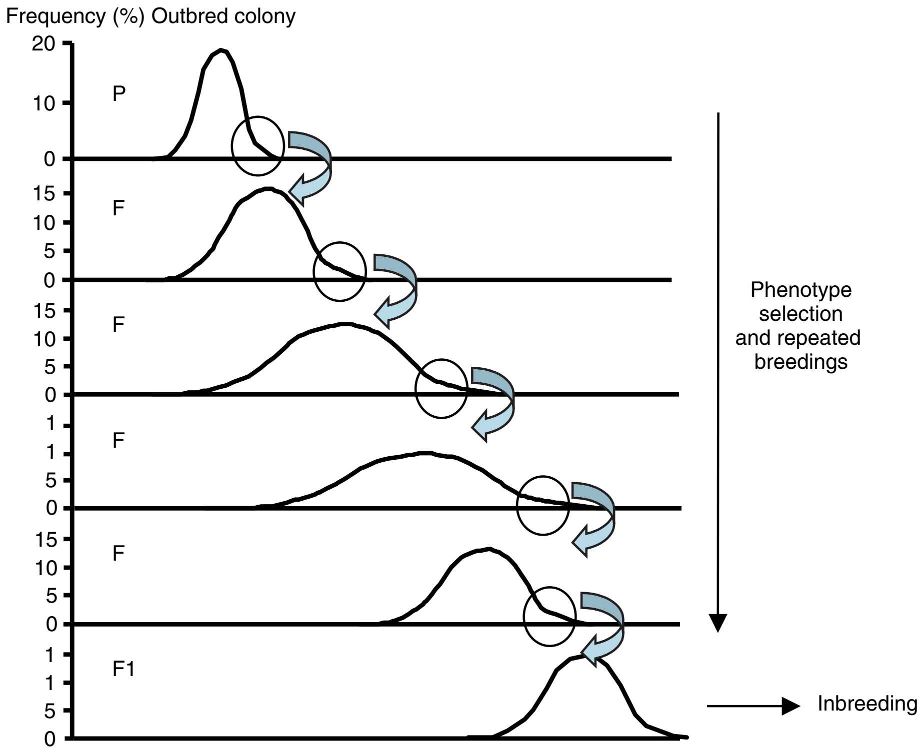

Figure 1 Selection of naturally occurring disease gene variants in inbred rats by phenotype screening and repeated breeding of outbred rats

(illustrated in Figure 1) is based on the assumption that naturally occurring alleles altering biological processes exist in outbred rats and can be concentrated in an inbred strain. A single pathophysiological criterion was applied for isolating animals carrying disease susceptibility or resistance alleles. Commonly used strains derive from either Wistar or Sprague-Dawley outbred stocks, and genetic diversity is therefore relatively limited.

Other rat models including chromosome substitution (consomic) strains, which are proposed as novel tools for assigning quantitative traits to an entire chromosome (Cowley *et al*., 2004), and congenic strains (described in Section 6.1) are being developed. Progress is also being made in the application of ENU mutagenesis and gene disruption technologies to the rat (Zan *et al*., 2003), which will undoubtedly have an important impact in physiological and functional genomics studies in the rat.

3. Rat genetic mapping panels

Most of the rat genetic studies are based on genetic and phenotypic analyses in classical segregating populations (F2 or first backcross cohorts). Crosses have

been generated using inbred strains either isolated from the same outbred stock (e.g., SHRxWKY, LHxLN, WKYxWKHA) or genetically unrelated, allowing increased polymorphism rate and the potential of contrasting alleles, and ultimately facilitating the detection and fine mapping of quantitative trait loci (QTLs) (*see* Article 11, **Mapping complex disease phenotypes**, Volume 3).

The panel of recombinant inbred (RI) strains derived from BN and SHR represents a permanent resource for QTL mapping (Pravenec *et al*., 1995). Although these strains primarily represent a mosaic of blood pressure (BP) contrasting alleles, other physiological characteristics in the founder strains (Table 1) provide opportunities for mapping multiple phenotypes and genotype-environmental interactions.

The rat genetically heterogeneous stock (HS), founded from BN/SsN, MR/N, BUF/N, M520/N, WN/N, ACI/N, WKY/N, and F344/N strains (Hansen and Spuhler, 1984), is in many respects similar to its mouse counterpart, and could be used to map the genetic basis of complex traits to subcentimorgan resolution (Mott and Flint, 2002). Well-established disease phenotypes in BN and F344 strains (Table 1) should make this panel amenable to QTL mapping.

4. Rat genetic and genomic resources

With the growing interest in disease gene mapping in the rat and comparative genomics, the production of rat genetic and genomic resources has closely followed those generated for the mouse. International efforts have progressively generated a large collection of rat microsatellite markers characterized for allele variations in strains commonly used in genetic studies (**http://www.well.ox.ac.uk/rat_mapping_resources**; **http://rgd.mcw.edu**). Polymorphism rates between strains vary from 20% for strains derived from the same outbred stock (e.g., SHRSP vs. WKY) to over 70% for genetically distant strains (e.g., SHR vs. BN or GK vs. BN). Results from polymorphism assays also showed the high genetic variability between colonies of supposedly identical strains (WKY, SHR, and SHRSP) (Bihoreau *et al*., 1997a). Three crosses (FHHxACI, SHRSPxBN, BNxGK) (Steen *et al*., 1999; Wilder *et al*., 2004) and a radiation hybrid (RH) panel (Steen *et al*., 1999; Watanabe *et al*., 1999) were used to localize the vast majority of markers in the rat genome.

The most significant recent developments in rat genomics are the completion of the rat genome sequence (Rat Genome Sequencing Project Consortium, 2004) and the emergence of rat single nucleotide polymorphism (SNP) markers (Zimdahl *et al*., 2004), which open important perspectives for refining genealogies of inbred rat strains and identifying disease genes.

5. Genetics of complex phenotypes in the rat

The multiple pathophysiological components participating in the onset and progression of complex diseases, their polygenic control, the involvement of environmental factors and gene–gene and gene–environment interactions underline the requirement of extensive biological screens for accurately assessing disease phenotypes (*see* Article 58, **Concept of complex trait genetics**, Volume 2). The possibility to

collect relatively large samples of biofluids and organs is a key element in rat quantitative genetic studies. To date, over 700 QTLs reflecting the effect of natural gene variants have been reported in the rat (**http://www.ensembl.org/Rattus_norvegicus**; **http://rgd.mcw.edu**). This section focuses on the most significant features of rat QTL studies illustrated in Figure 2, and their contribution to our understanding of the etiology of multifactorial diseases.

5.1. Susceptibility to experimentally induced disorders

Knowledge of strain-specific susceptibility and resistance to experimentally induced disorders (Table 1) has been particularly useful to investigate the genetics of common autoimmune and inflammatory processes and cancers in rat crosses. Immunization of LEW and DA rats with spinal cord tissue or myelin oligodendrocyte glycoprotein results in experimental autoimmune encephalomyelitis (EAE), a model of multiple sclerosis. Rheumatoid arthritis (RA) is induced in the DA rat by injection of cartilage antigens (collagen-induced arthritis – CIA) or nonimmunogenic substances with strong adjuvant effects (pristane-induced arthritis – PIA or oil-induced arthritis – OIA). Over 30 QTLs regulating RA susceptibility, chronicity, and severity have been mapped in crosses derived from the DA rat and either CIA-resistant (F344, BN, ACI, E3), PIA-resistant (E3, F344, LEW.1AV1), or OIA-resistant (LEW.1AV1) strains (Griffiths and Remmers, 2001; Olofsson *et al*., 2003a). The overlap between RA and EAE QTLs in the DA rat suggests the influence of common genes (Dahlman *et al*., 1998; Bergsteinsdottir *et al*., 2000). BN-specific enhanced IgE responsiveness to injections of aurothiopropanol sulfonate is under polygenic control (Mas *et al*., 2000). Susceptibility and resistance to dimethylbenzanthracene-induced mammary carcinogenesis, hepatocellular carcinoma, and estrogen-induced pituitary tumors have been mapped in the rat genome (Wendell *et al*., 2000; Lan *et al*., 2001; De Miglio *et al*., 2004).

In the field of type 2 diabetes mellitus (T2DM) and obesity, neonatal injection of streptozotocin (STZ), an alkylnitrosourea that specifically destroys pancreatic insulin-producing β-cells, dietary changes (e.g., high fat and cafeteria diets) and lesions of ventromedial hypothalamus nuclei have been used, primarily in rats, to induce permanent diabetes, insulin resistance, and obesity. Strain-specific resistance/susceptibility to diabetes/obesity induced by STZ or dietary changes, which has been applied to QTL mapping in mice, remains to be tested in the rat.

5.2. Spontaneously occurring disease phenotypes

Although neurobehavioral phenotypes are defined by procedures primarily developed in rats, only two studies have successfully explored the genetics of anxiety and activity in the rat (Moisan *et al*., 1996; Fernandez-Teruel *et al*., 2002). Invasive methods routinely used in rats to acquire repeated and prolonged cortical electroencephalogram recording provide interesting perspectives in neurogenetics as qualitative and quantitative information on spike-wave discharges (SWD) can be determined. Recent studies have demonstrated that SWD phenotypes in GAERS

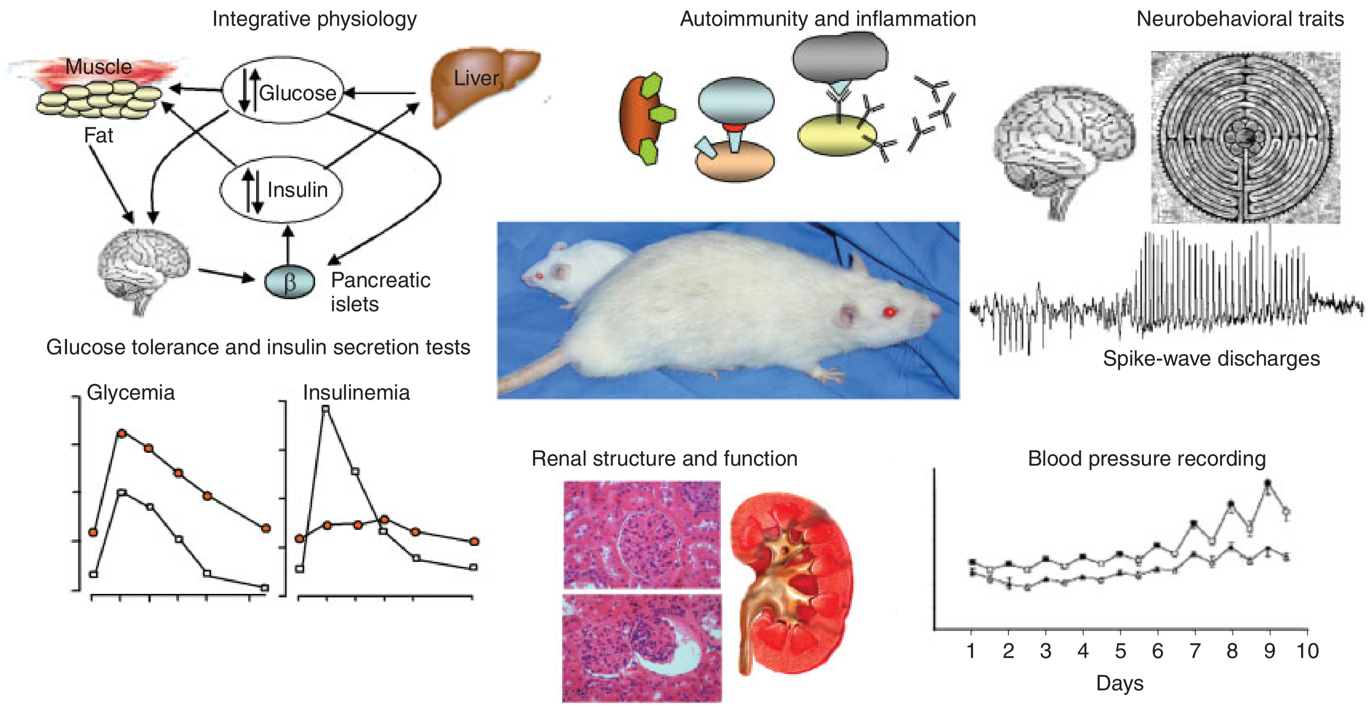

Figure 2 Examples of phenotypes mapped to the rat genome by QTL analysis. The size of the rat allowed the quantification of subphenotypes using procedures that are often technically difficult to perform in the mouse (in the background)

and WAG/Rij rat models of spontaneous absence seizures are under polygenic control and that different loci regulate SWD subtypes in the WAG/Rij rat (Gauguier *et al*., 2004; Rudolf *et al*., 2004).

Studies in the Bio-Breeding Diabetes Prone (BBDP) and Komeda Diabetes Prone (KDP) strains have generated a vast amount of information on the genetic and immunological basis of type 1 diabetes mellitus (T1DM) (autoimmune destruction of pancreatic beta-cells resulting in insulinopenia and severe hyperglycemia) (Jacob *et al*., 1992; Ramanathan and Poussier, 2001 Yokoi *et al*., 2002; Ramanathan *et al*., 2002).

Three rat strains (*Cy*, *Pck*, and *Wpk*) develop renal pathologies closely resembling human polycystic kidney diseases (PKD). Interestingly, modifier genes controlling disease variable severity, which is a phenomenon described in human PKD, have been mapped in the *Cy* rat (Bihoreau *et al*., 1997b; Bihoreau *et al*., 2002).

Essential hypertension (*see* Article 63, **Hypertension genetics: under pressure**, Volume 2) and T2DM (*see* Article 57, **Genetics of complex diseases: lessons from type 2 diabetes**, Volume 2) are among the best examples of inherited quantitative phenotypes that have been extensively studied in the rat. The following sections emphasize the importance of the laboratory rat for acquiring intermediate phenotypes relevant to these disorders, which can be used in QTL detection experiments.

5.3. Genetic determinants of hypertension in the rat

Genetic studies of BP control have pioneered QTL mapping in the rat. The first successful localization of a genetic locus controlling BP quantitative variations was obtained with an RFLP marker of the renin gene in an SSxSR cross (Rapp *et al*., 1989). This line of research gained momentum with the increasing number of rat genetic markers, which allowed genome-wide scans of loci controlling cardiovascular traits in all spontaneously hypertensive rat strains (Rapp, 2000). The first evidence of the polygenic control of BP variables was obtained in a SHRSPxWKY cross (Hilbert *et al*., 1991; Jacob *et al*., 1991).

Our current knowledge of BP genetics in rats is based on data from over 25 different crosses, which allowed the mapping of over 190 QTLs in the rat genome (**http://rgd.mcw.edu**). The strongest evidence of replicated linkage to BP was obtained in chromosomes 1, 2, 10, and 13 (Rapp, 2000). Direct comparisons between results from these studies are problematic because different experimental conditions (e.g., age at phenotyping, methods for BP recording) and strain combinations were used. In this respect, extensive genetic studies in hybrids derived from SS rats bred to different strains, which were maintained in identical conditions and characterized for BP using identical procedures, strongly suggest that the genetic background of normotensive strains in experimental crosses influences QTL replication (Rapp, 2000).

A strategy of BP phenotype dissection initiated by Dubay *et al*. (1993) in hybrid rats of a segregating population was later extended to multiple BP-related biological parameters (Stoll *et al*., 2001) and phenotypes relevant to end-organ complications.

Although rat BP QTLs are often associated with effects on heart weight and left ventricular mass (Rapp, 2000), cardiac hypertrophy is a common but not inevitable complication of hypertension. Data from crosses between normotensive strains provide confirmatory evidence for the independent genetic control of cardiac mass and BP (Sebkhi *et al*., 1999; Gauguier *et al*., 2005). The existence of a causal link between hypertension and stroke in the SHRSP strain is also debated. The relationship between susceptibility to stroke and hypertension was addressed in two genetic studies, which gave fundamentally different results (Rubattu *et al*., 1996; Jeffs *et al*., 1997). Renal damage is present in almost all hypertensive rat strains (Rapp, 2000). Results from genetic studies in hypertensive rats strongly suggest that genetic factors independent of BP influence the progression and possibly the onset of renal disease (Brown *et al*., 1996; Gigante *et al*., 2003; Garrett *et al*., 2003). Of note, MNS rats develop glomerulosclerosis and proteinuria in the absence of hypertension.

Among abnormal vascular phenotypes observed in inbred rats, ruptures of the aortic internal elastic lamina (AIEL) spontaneously occur in BN rats, whereas other normotensive strains are devoid of these lesions (Behmoaras *et al*., 2005). Genetic studies in the BN rat allowed the mapping of independent QTLs for AIEL lesions (Harris *et al*., 2001) and variations of aortic elastin, collagen, and cell protein contents (Gauguier *et al*., 2005).

5.4. Type 2 diabetes mellitus, insulin resistance, and obesity

The laboratory rat is particularly appropriate for investigating the multiple metabolic and hormonal defects occurring in different tissues (pancreas, liver, fat, muscles) that contribute to insulin secretion deficiency and insulin resistance and ultimately hyperglycemia. Polygenic inheritance of diabetes-related traits has been demonstrated in rat models of spontaneous T2DM (GK, OLETF, SDT) (Galli *et al*., 1996; Gauguier *et al*., 1996; Kanemoto *et al*., 1998; Masuyama *et al*., 2003). The dissection of diabetes in subphenotypes in a GKxBN cross allowed the detection of independent QTLs for fasting glycemia and insulinemia, glucose tolerance, insulin secretion in response to glucose or arginine in vivo, adiposity and body weight (Gauguier *et al*., 1996). The genetics of other important pathophysiological components of diabetes in the GK strain (impaired beta cell, reduced β-cell mass function, dyslipidemia) is not explained by these results. A remarkable feature in the genetics of diabetes in these strains is the consistent mapping of diabetes QTLs to the same regions of chromosomes 1 and 2, despite differences in the procedures applied to assess glucose homeostasis and in the control strain (BN or F344) used to generate the experimental cross (Galli *et al*., 1996; Gauguier *et al*., 1996; Masuyama *et al*., 2003).

Among the common vascular complications of T2DM (neuropathy, retinopathy, and nephropathy), renal structural damage and albuminuria have been described in all rat models of spontaneous or experimentally induced diabetes and/or obesity, suggesting a permissive role of hyperglycemia, obesity, or hyperlipidemia on susceptibility to renal disease. The relative contribution of specific genetic factors and hyperglycemia on renal damage has not been addressed in diabetic models.

6. Strategies and tools for post QTL mapping studies

QTL detection in experimental crosses or consomic strains is only a preliminary stage in the genetic analysis of a quantitative phenotype. Further investigations are required to confirm the existence of a QTL, refine its chromosomal localization, and most importantly test the pathophysiological consequences of the underlying gene variant(s).

Congenic strains carrying segments of chromosomes harboring a QTL introgressed onto a permissive background (usually the reciprocal strain in the experimental cross) currently provides the most reliable way of progressing from mapping of a QTL to identification of the underlying gene (Rogner and Avner, 2003). Congenics designed using various strain combinations are now widely used for dissecting rat QTLs (Table 2).

From a fundamental perspective, the phenotypic impact of QTLs can be "weighed" by comparing quantitative traits in congenic strains and in segregating

Table 2 Rat congenic panels designed to dissect the pathophysiology of complex phenotypes and fine map QTL. Standard nomenclature (Recipient.Donor) indicates the origin of the donor alleles (QTL target) introgressed onto the genetic background of the recipient strain. A series of congenic strains were generally derived for different regions covering the QTL

Primary phenotype	Congenic series	Chromosomes
Hypertension	SHR.BN	1,5,8,13,19
	BN.SHR	2
	SHR.WKY, WKY.SHR	1,2,Y
	SHRSP.WKY	1,2
	WKY.SHRSP	2,10
	SS/jr.LEW	1,5,8,10,17
	SS/jr.MNS	2,10
	SS/jr.WKY	2
	SS/jr.SR/jr	3,7,9,13
	MNS.MHS, MHS.MNS	1 (*Add3*),4 (*Add2*),14 (*Add1*)
	SBN.SBH, SBH.SBN	1
Type 1 diabetes	BBDR.BBDP	4 (*lyp*)
	BB/OK.SHR	1,6,18,X
	F344.BBDP	4 (*lyp*)
Type 2 diabetes	BN.GK	2,8
	F344.GK	1
	F344.OLETF	5,7,8,9,11,12,14,16
	OLETF.F344	1
Cancer	WF.COP	2
	BN.F344, WF.WKY	5
Atopy	LEW.BN, BN.LEW	9,10

Arthritis	DA.F344, LEW1AV1.DA	10
	DA.E3	4,12
	DA.LEW1AV1, LEW1AV1.DA	4
	DA.PVG1AV1, PVG1AV1.DA	4
EAE	ACI.DA	10
Renal failure	ACI.FHH	1

populations (Garrett *et al*., 1998). Furthermore, studies in double congenics, which contain genomic regions covering two different QTLs, can help evaluate functional relationships (epistasis) between QTLs (Rapp *et al*., 1998). Congenics also provide opportunities to test the phenotypic impact of disease variants at a QTL when introgressed onto different genetic backgrounds.

From a biological angle, studies in congenics can test gender effects and gene-environment interactions, and characterize disease onset and progression using different or more refined phenotype procedures than those used in the original cross (Wallis *et al*., 2004). For example, a fundamental role of gene(s) at a RA QTL on arthritis susceptibility and progression was deduced from the reduced arthritogenic responses to collagen, pristane, squalene, and adjuvant in DA.PVG congenics (Backdahl *et al*., 2003). The most important outcome of studies in congenics lies in the possibility to translate statistical estimates supporting QTL localization to a genomic interval, thus defining anchor points in the rat genome sequence for candidate gene identification (see Section 7.2). However, the existence of variants in multiple genes contributing to a QTL effect is a hallmark of almost all examples of QTL dissection in congenics, making the selection of candidate genes problematic. Several genes independently contribute to rat QTLs for tumor resistance (Haag *et al*., 2003), hypertension (Garrett *et al*., 2001; Saad *et al*., 2001; Frantz *et al*., 2001), T2DM (Wallace *et al*., 2004), and atopy (Mas *et al*., 2004).

Among other strategies allowing fine QTL mapping, advanced intercross lines have been used for separating closely linked EAE QTLs (Jagodic *et al*., 2004). Genetic studies in the rat HS can also speed up disease gene identification (see Section 3), providing that the founder strains exhibit marked differences in phenotypes of interest. However, these strategies give limited information on the phenotypic effects of the causative gene variants.

Profiling gene expression is a powerful strategy for assisting the selection of candidate genes in a congenic interval. Commercial and custom arrays of oligonucleotides are now available for interrogating the level of tens of thousands of known and predicted rat transcripts. A major problem with the application of this technology to complex traits such as T2DM is knowing which tissue (pancreatic islets, liver, muscles, fat, nervous tissues) should be examined for differential gene expression. It can nevertheless be resolved in the rat by physiological studies that will indicate specific target tissue(s) and experimental conditions. The large amount of RNA that can be obtained from rat tissues and structurally or functionally different regions of an organ is also an advantage. Proteomics, which still requires relatively large amounts of biological material, is also an attractive technology for selecting candidate genes in rat congenic intervals.

7. Disease gene identification in rat models

A growing number of genes responsible for monogenic and polygenic traits have been identified in the rat (Table 3).

Table 3 Molecular basis of Mendelian disease and complex trait genes in rat models

Gene	Description	Disease strain	Mutation or sequence variation	Phenotype	References
Atp7b	Copper transporting ATPase	LEC	Partial deletion	Autosomal recessive hepatocellular necrosis	Wu *et al*. (1994)
Cblb	Casitas B-lineage lymphoma B	KDP	Nonsense mutation (Arg455X)	Type 1 diabetes	Yokoi *et al*. (2002)
Csf1	Macrophage colony stimulating factor	LEW (*tl*)	10-bp repeat insertion	Autosomal recessive osteopetrosis	Dobbins *et al*. (2002)
Cd36	Fatty acid translocase	SHR	Chromosomal deletion	Insulin resistance	Aitman *et al*. (1999)
Cyp11b1	11 beta-hydroxylase	SS/jr	Multiple amino acid changes	High blood pressure	Cicila *et al*. (1993)
Ide	Insulin degrading enzyme	GK	Missense variants (H18R, A890V)	Insulin resistance, glucose intolerance	Fakhrai-Rad *et al*. (2000)
Ian4	Immune-associated nucleotide 4	BBDP	Frameshift mutation in exon 3	Autosomal recessive lymphopenia	MacMurray *et al*. (2002), Hornum *et al*. (2002)
Lepr	Leptin receptor	Zucker (*fa*)	Missense mutation (Gln129Pro)	Autosomal recessive obesity	Phillips *et al*. (1996)
Ncf1	Neutrophil cytosolic factor 1	DA	Coding variants (M106V, M153T)	Arthritis severity	Olofsson *et al*. (2003b)
Mertk	Receptor tyrosine kinase	RCS	Frameshift mutation	Autosomal recessive retinal dystrophy	D'Cruz *et al*. (2000)
Pax-6	Homeobox paired box-6	rSey	Single base (G) exonic insertion	Autosomal recessive impaired brain development	Matsuo *et al*. (1993)
Pkhd1	Fibrocystin/polyductin	SD (*Pck*)	Splicing change (IVS35-2A-T)	Autosomal recessive PKD	Ward *et al*. (2002)
Ship2	Type-II SH2-domain-containing inositol 5-phosphatase	GK, SHR	Missense mutation (R1142C)	Insulin resistance	Marion *et al*. (2002)

7.1. Monogenic models

Recessive obesity in the Zucker *fatty* rat develops as a consequence of an amino acid substitution in the leptin receptor gene, which is also mutated in the *db/db* mouse (Phillips *et al*., 1996). Retinal degeneration in the Royal College of Surgeons (RCS) rat is caused by a mutation in a gene encoding a receptor tyrosine kinase, which leads to a loss of photoreceptors (D'Cruz *et al*., 2000). The *tl* (toothless) osteopetrotic rat carries a 10-bp insertion within the coding sequence of the macrophage colony stimulating factor gene (Dobbins *et al*., 2002). Autosomal recessive PKD in the PCK rat is caused by a splicing change in the fibrocystin/polyductin protein (Ward *et al*., 2002). Lymphopenia in the BBDP rat is caused by a frameshift mutation in the gene *Ian4* (also called *Ian5*) involved in immune mechanisms and the regulation of apoptosis (MacMurray *et al*., 2002; Hornum *et al*., 2002).

7.2. Polygenic models

Two T1DM susceptibility genes have been identified by positional cloning in BB and KDP rats. *Iddm2* maps to the $RT1^u$ haplotype of the class II MHC locus in the BB strain, but the precise mechanisms through which it predisposes to T1DM remains unknown (Ellerman and Like, 2000). A nonsense mutation in an ubiquitin-protein ligase involved in tyrosine kinase signaling pathways accounts for the T1DM locus *Kdp1* in the KDP rat (Yokoi *et al*., 2002).

Fine QTL mapping in congenics has proved an important strategy for detecting functional gene variants explaining, at least in part, central features of hypertension, T2DM, RA, and insulin resistance QTLs. In the SS strain, the causative role of amino acid substitutions in the 11 beta-hydroxylase (*Cyp11b1*) protein (Cicila *et al*., 1993) was eventually validated in a SS.SR congenic strain (Garrett and Rapp, 2003). Combining gene transcription profiling and phenotype investigations in SHR/*NCrj* congenic strains, a deletion in a fatty acid translocase gene (*Cd36*) was identified, which is probably relevant to insulin resistance in isolated adipocytes (Aitman *et al*., 1999). The absence of the mutation in the SHRSP/*Izm* colony believed to be the founder strain of SHR and SHRSP strains (Gotoda *et al*., 1999) suggests the occurrence of a de novo mutation in the SHR/*NCrj* strain. Functional variants have been recently described in the GK rat in genes localized in diabetes QTLs in rat chromosome 1 (Galli *et al*., 1996; Gauguier *et al*., 1996). Variants in the insulin degrading enzyme account for a diabetic phenotype in a F344.GK congenic strain (Fakhrai-Rad *et al*., 2000). A functional mutation specific to the GK and SHR strains was identified in the gene *Ship2*, which is involved in insulin stimulated glucose transport and lipid synthesis (Marion *et al*., 2002). In DA rats, a polymorphism in the neutrophil cytosolic factor gene (*Ncf1*) causes a decrease in oxygen burst, resulting in severe arthritis (Olofsson *et al*., 2003b).

8. Translating rat disease genes to human genetics

Rat genomic sequence data (Rat Genome Sequencing Project Consortium, 2004) have dramatically enriched the resources required for comparative genome

analyses between rat, mouse, and human, which were established previously by chromosomal mapping of rat gene and EST sequences (Watanabe *et al*., 1999; Wilder *et al*., 2004). Given the high degree of conservation of synteny and gene order in the three species, human chromosomal regions homologous to rat QTLs and congenic intervals can be easily identified.

A striking concordance has often been reported between the localization of rat QTLs and susceptibility loci for human essential hypertension (Stoll *et al*., 2000), epilepsy (Pinto *et al*., 2005), T2DM (Wallace *et al*., 2004), atopy (Mas *et al*., 2000), renal disorders (Bihoreau *et al*., 2002), and autoimmune/inflammatory diseases (Griffiths and Remmers, 2001). These findings emphasize the importance of investigations in the rat for prioritizing genetic studies in human to specific chromosomal regions.

Ultimately, genetic and functional genomic studies in rats can generate gene targets to be tested in human genetics. Mutations in the human orthologs of rat *Mertk* and *Pck* (PKHD1) have been found in patients with retinitis pigmentosa (Gal *et al*., 2000) and PKD (Ward *et al*., 2002), respectively. In the field of multifactorial disorders, the strongly significant association between an haplotype in SHIP2 (see Section 7.2) and components of the insulin resistance syndrome (T2DM, obesity, and hypertension) is the only example of successful translation of results from rat quantitative genetics to human complex diseases (Kaisaki *et al*., 2004).

9. Conclusions

Building on the wealth of physiological information that can be obtained in the rat, genetic loci cosegregating with phenotypes underlying key pathological features of human multifactorial disorders have been mapped in the rat genome. Ongoing studies in congenic strains have validated most rat QTLs, owing to their relatively modest phenotypic effects in experimental crosses, and reports identifying rat disease gene variants are now emerging in the literature. Parallel cross-disciplinary phenotyping in existing inbred rat strains and emerging congenic and consomic panels should further enhance the input of rat models in quantitative genetics research. Rat genomic sequence data and progress in comparative genomics will enhance the power of studies in the rat and lead, synergistically with studies in mice (*see* Article 38, **Mouse models**, Volume 3), to a better understanding of the role of natural variants in mechanisms involved in the etiology of human complex diseases.

Specialist Review

Farm animals

Leif Andersson
Uppsala University, Uppsala, Sweden

1. Introduction

Genome research in farm animals is justified because it may lead to important practical applications in the animal industry. A number of diagnostic DNA tests that are widely used have already been developed. Most of these concern monogenic traits or disorders but there are also several examples where a Quantitative Trait Loci (QTL) affecting a multifactorial trait has been exploited in the animal industry. Most of the QTL applications have been based on the principle of Marker Assisted Selection (MAS) where a marker bracket is used to alter the frequency of QTL alleles for which the molecular nature are unknown. There are some cases like *DGAT* controlling milk yield in cattle (Grisart *et al*., 2002; Grisart *et al*., 2004; Winter *et al*., 2002) and *IGF2* affecting muscle mass in pigs (Braunschweig *et al*., 2004; Van Laere *et al*., 2003) where the underlying mutation for a QTL has been revealed and a direct diagnostic test can be applied. However, practical animal breeding still relies primarily on traditional phenotypic selection despite the significant progress in animal genomics but this may change in the near future due to drastically reduced costs for high-throughput analysis of genetic markers.

Genome research in farm animals will contribute to our understanding of gene and genome evolution and will provide new basic knowledge, in particular, concerning the molecular basis for phenotypic variation. Historically, research on domestic animals has contributed considerably to basic biology. Charles Darwin used domestic animals as a proof-of-principle for his theory on phenotypic evolution caused by natural selection (Darwin, 1859). Furthermore, the inheritance of coat color in domestic animals was among the first traits to be used for genetic studies soon after Mendel's laws of heredity were rediscovered in the beginning of the twentieth century (Bateson, 1902; Spillman, 1906). Farm animals are not particularly well suited for studying simple monogenic disorders. Such deleterious mutations are rare in domestic animals since they tend to be eliminated from the breeding population. The best organisms for studying the phenotypic consequences of deleterious mutations with large phenotypic effects are humans, since such mutations often lead to clinical disorders, or experimental animals, since systematic screenings for induced deleterious mutations can be performed. However, for those mutations where one needs to compare hundreds of individuals with different genotypes to reveal a phenotypic effect, neither human materials nor

mutation screenings in model organisms are ideal. Most phenotypic variations in all species are due to mutations with mild phenotypic effects. Here farm animals provide unique opportunities because these species have been genetically modified by selective breeding, a process that has involved millions of individuals for thousands of years. In fact, no experimental organism has been genetically modified to the same extent as farm animals. Thus, farm animal populations harbor rich collections of nonmorbid mutations affecting phenotypic characters. Domestication can be viewed as an adaptation to a new environment. We now have the tools to unravel the molecular basis for this process. This research can shed light on many of the unanswered questions concerning the basis for phenotypic evolution. For instance, to which extent does loss-of-function mutations contribute to phenotypic evolution (Olson, 1999)? How important are regulatory mutations (King and Wilson, 1975) and epistatic interactions (Carlborg and Haley, 2004)? Does epigenetic inheritance play a significant role (Bjornsson *et al*., 2004)?

Genome research in farm animals can also make important contributions to human medicine, in particular, as regards metabolism, immune response, susceptibility to infectious disease, and reproductive traits. Metabolic traits are often altered in domestic animals since a common breeding goal is to promote the allocation of energy and nutrients into animal products such as meat, milk, and eggs. A good example is fat deposition in pigs. Before 1900, there was a strong preference for fat pigs because a high energy content in animal products was desired. However, during the last 50 years, there has been a stronger and stronger consumer demand for pig meat with low fat content, and the fat deposition has successively been reduced. In a cross between the wild boar and domestic pigs, it became apparent that the wild boar carried QTL alleles favoring fat deposition (Andersson *et al*., 1994). A high fat deposition is adaptive in the wild boar since it must use stored fat to survive periods of starvation. This situation resembles very much the "thrifty gene" hypothesis, which implies that a major reason for the problem with obesity and metabolic disorders in humans is that alleles favoring fat deposition had a selective advantage during periods in the past with inappropriate food supplies (Neel, 1962). Thus, the genes that once were associated with a selective advantage are today causing metabolic disorders. Genetic analysis of wild boar/domestic pig intercrosses can shed light on the genetic regulation of fat deposition and may reveal novel strategies for treatment of obesity and metabolic disorders in humans. Similarly, the intramuscular fat content has often been altered in meat-producing animals and fat content in skeletal muscle is of considerable interest in relation to the development of insulin resistance and Type II diabetes (Friedman, 2004). Disease resistance and immune response are other traits that have been altered during domestication as part of the adaptation to the farm environment with its higher density of animals and higher exposure to pathogens. There are many local breeds, in particular in tropical countries that have evolved resistance or tolerance to certain pathogens. Such breeds provide a largely unexploited resource for studies of the genetic basis for host–pathogen interactions. Finally, reproductive traits, such as age of sexual maturation, litter size, and seasonality, have been extensively modified in farm animals and genetic studies may shed light on the genetic regulation of reproduction. However, both disease resistance and reproductive traits are often difficult to study genetically due to a strong environmental influence on these traits.

2. Evolutionary history

All farm animals have, from an evolutionary point of view, a young history as domestications occurred within the last ∼10 000 years. Most of the neutral sequence polymorphisms we observe in these species have an origin well before domestication as can be shown by estimating the frequency of nucleotide substitutions that has accumulated since domestication. The neutral substitution rates in human and mouse have been estimated at 2.2×10^{-9} and 4.5×10^{-9} per site per year respectively (Mouse Genome Sequencing Consortium, 2002). Using the mean of these two figures, we can estimate that the average frequency of neutral nucleotide substitutions that has occurred between two haplotypes that diverged 10 000 years ago should be $\sim 6.5 \times 10^{-5}$ per site, that is, 6–7 single nucleotide polymorphisms (SNPs) per 100 kb. The average pairwise SNP rate within and between breeds of domestic chicken has recently been estimated at 5–6 SNPs/kb (International Chicken Polymorphism Map Consortium, 2004), and we expect that the corresponding figure for other domestic animals will be in the range 1–5 SNPs/kb. Thus, only a few percent of the neutral nucleotide substitutions we observe between two random chromosomes are expected to have occurred subsequent to domestication. Consequently, if one makes sequence comparisons between a wild ancestor and the corresponding domestic animals, for those species where the wild ancestor has not been extinct (e.g., red jungle fowl and wild boar), one finds that few sequence variants are unique for domestic populations. The exceptions are of course those mutations that have been under strong positive selection, or neutral sites in the near vicinity of selected sites, where a mutation may be common in the domestic animal but rare or completely absent in the wild ancestor. It is still an open question to which extent the response to phenotypic selection in domestic animals is due to mutations that were present in the wild ancestor before domestication or mutations that have occurred subsequent to domestication. The latter explanation is probably important, at least for mutations with major phenotypic effects. Those would often be associated with a selective disadvantage in the wild population.

Accumulating evidence shows that several farm animals originate from distinct subpopulations of the wild ancestor that diverged from each other long before domestication (Bruford *et al*., 2003). This is the case for cattle, which originates from two subspecies, denoted *Bos taurus* and *Bos indicus*, corresponding to cattle with or without hump and with a European and an Asian origin, respectively (Bruford *et al*., 2003). Similarly, pig domestication involved wild boar populations from both Europe and Asia (Giuffra *et al*., 2000), the clear separation of the European and Asian ancestor is evident from an average sequence divergence of 1.2% for the entire mitochondrial DNA (Kijas and Andersson, 2001). Therefore, modern breeds of farm animals may have a hybrid origin. This is well documented for African cattle (Freeman *et al*., 2004) and for several European breeds of domestic pigs (Giuffra *et al*., 2000). As an example, the characterization of the *IGF2* locus in pigs revealed that European domestic pigs carried *IGF2* haplotypes originating from both a European and an Asian wild ancestor and the two haplotype forms showed a sequence divergence of about 1% (1 SNP/111 bp; Van Laere *et al*., 2003).

3. Genomic resources

Basic resources for genome research such as large sets of genetic markers (microsatellites and SNPs), medium dense linkage maps, radiation hybrid panels, and BAC libraries have been established for all farm animals. A compilation of databases and websites providing information of these resources is given in Table 1. It should be noted that goat, sheep, and cattle are all ruminants and fairly closely related. Goat and sheep diverged about 5 million years before present and their common ancestor diverged from the cattle lineage about 20 million years before present. This means that genome projects in sheep and goat can take advantage of genome resources and information developed for cattle, the most well studied of these three species.

The ultimate genetic map is of course the complete genome sequence of the target species. A high-quality draft genome sequence at 6.6X coverage has recently been released for chicken as the first domestic animal and the first bird to have its genome sequenced (International Chicken Genome Sequencing Consortium, 2004). The data were generated by sequencing a red jungle fowl female from a partially inbred line. A comprehensive search for sequence polymorphism was carried out in parallel by shot-gun sequencing of three domestic birds, a layer, a broiler,

Table 2 Animal resources for genome research in farm animals

Type of population	Traits[a]	Cost	Population size
Commercial	Standard	+	+++
Commercial	Special	++ − +++	++
Experimental herds	Special	++	+[b]
Experimental crosses	Special	+++	+[b]

[a]Standard traits refer to those traits registered for breeding purposes at no extra cost for the research project.
[b]Large experimental populations (thousands of individuals) may be used for chicken and, in some cases, also for pigs.

and a Silkie, each to 0.25X coverage (International Chicken Polymorphism Map Consortium, 2004). This revealed as many as 2.8 million SNPs for the chicken. A preliminary draft assembly at 3X coverage for cattle was released during 2004 and a high-quality draft genome sequence will be available by 2005 (**http://www.hgsc.bcm.tmc.edu/projects/bovine/**). A genome sequence with ∼1X coverage has been generated for the pig but the data are not yet publicly available (M. Fredholm, personal communication). No initiatives have yet been taken to sequence the genomes of goat, sheep, or horse.

4. Strategies for mapping trait loci

There are two routes for mapping trait loci in farm animals, namely, by using existing pedigrees from commercial populations or by generating experimental pedigrees (Table 2). Genome research in cattle and horse are almost exclusively based on existing pedigrees due to the high cost for making experimental pedigrees that are sufficiently large for gene mapping experiments. The chicken is the other extreme where almost all mapping efforts are carried out with experimental populations. The use of commercial populations can be very cost-effective since it is possible to collect large families with available phenotypic data at no other cost than those associated with sample collection. The phenotypic data are then limited to the traits recorded for breeding purposes such as milk quantity and milk composition in cattle or growth and meat content in pigs. More detailed phenotypic characterization can to some extent be added for research purposes. The collection of very large multigeneration families facilitates powerful statistical analysis. It is also possible to utilize the breeding values calculated on the basis of progeny testing that provide very accurate measures of the genotype of sires based on phenotypic data from a large number of progeny. This has been widely used for QTL mapping in dairy cattle based on the granddaughter design where the segregation of breeding values from grandsires to sons is evaluated (Georges *et al*., 1995; Weller *et al*., 1990).

The use of experimental populations has the advantage that environmental variation is better controlled and much more detailed phenotypic recordings can be made, but the maintenance of experimental populations are costly. Cross-breeding experiments are even more costly, but very powerful. Linkage analysis is then

facilitated by the high heterozygosity in the F_1 generation and the fact that the linkage phase between alleles at marker and trait loci is often the same in all F_1 animals. However, this is not always true since the founder populations are usually outbred, which means that some segregation at QTLs may occur within lines. Cross-breeding experiments are the only way to map trait loci that have been under very strong selection and therefore are fixed within lines.

An important difference between human genetics and animal genetics is that there is less genetic heterogeneity at trait loci in farm animals. The paradigm in human genetics is that there are many different mutations causing the same inherited disorder in different families. The reason for this is of course that there are many ways to knock out gene function and with the huge current effective population size in humans, many new deleterious mutations are generated each generation. In farm animals, it is much more common that one finds a single or a few causative mutations at trait loci. This is particularly true for those mutations that have been under strong phenotypic selection since they are spread rapidly across the population. The presence of a widespread causative mutation tracing back to a common ancestor facilitates the use of identical-by-descent (IBD) mapping to identify a common shared haplotype harboring the causative mutation (Andersson and Georges, 2004). The identification of a Quantitative Trait Nucleotide (QTN) at the *IGF2* locus underlying a major QTL in pigs is an excellent example where an IBD approach was used to map the causative mutation to a ∼15-kb interval (Van Laere *et al*., 2003).

5. Monogenic trait loci

The identification of genes underlying monogenic trait loci in farm animals is today often straightforward if a sufficient pedigree and/or population material is available for linkage or association analysis, respectively. In fact, the optimal design for mapping trait loci is to combine linkage and IBD mapping to achieve a high-resolution localization. A list of interesting trait loci for which the underlying causative mutation has been identified is given in Table 3.

The identification of causative genes and mutations are done by positional candidate cloning or by classical positional cloning. Positional candidate cloning is becoming more and more powerful with the continuous improvement of the functional annotation of vertebrate genes. This strategy implies that the trait locus is first mapped to a specific chromosomal region, then gene annotation data across species are extracted, a screen for mutations is done for the best candidate genes, and finally the candidate mutations are evaluated by genetic and functional analysis. For all species, except chicken, this approach must still involve a comparative mapping effort in order to take advantage of the near-complete genome sequences available for other species. This is usually straightforward since there is a high degree of conserved synteny and conserved gene order among closely related species like two mammalian species. However, it is not uncommon that linkage mapping assigns a locus to a region that harbors no obvious candidate gene because the function of the causative gene is still poorly understood. If so, a high-resolution mapping is required to reduce the critical

[a]These are apparently mutations in cis-regulatory element that influence the expression of one or more genes.

interval as much as possible and an IBD approach may be required to reduce the interval to a region significantly smaller than 1 Mb. This requires access to both sufficient animal material and high-density marker maps. The current efforts to generate complete genome sequences and large collections of polymorphisms, as recently accomplished for the chicken (International Chicken Genome Sequencing Consortium, 2004; International Chicken Polymorphism Map Consortium, 2004), will greatly facilitate the molecular characterization of trait loci in farm animals.

6. Quantitative trait loci (QTL)

A QTL is defined as a chromosomal region harboring one or several mutations affecting a multifactorial trait (Lynch and Walsh, 1998). The first genome scans for QTL detection in farm animals were carried out 10 years ago and involved growth and fatness traits in a wild boar/domestic pig intercross (Andersson *et al*., 1994) and milk production traits in dairy cattle (Georges *et al*., 1995). Since then, numerous QTL studies in farm animals have been reported. The statistical methodology for QTL analysis using different experimental designs is well established (Hoeschele, 2003; Jansen, 2003; Lynch and Walsh, 1998). User-friendly, Web-based software for QTL analysis is also available (Seaton *et al*., 2002). Perhaps the most important

component in the design of a QTL study is the size of the experiment since a material with too few progeny will lead to a low statistical power. The consequence of an underdimensioned experiment is that no QTLs are detected or that the estimated effects of the detected QTLs are inflated (Goring *et al*., 2001; Mackinnon and Georges, 1992); see Lynch and Walsh (1998) for recommendations on the required sample size for QTL detection. A general recommendation is that the larger sample size, the better, as a large sample size will allow a more sophisticated and powerful statistical analysis including the detection of genetic heterogeneity and epistatic interaction.

However, the major challenge is not to find QTLs but to unravel the underlying gene(s) and mutation(s) (Andersson and Georges, 2004). Gene identification is difficult for several reasons. First, the precision in QTL mapping is poor because the phenotype is determined by multiple QTLs in combination with environmental factors. Thus, there is no simple one-to-one relationship between a QTL and a phenotype. Second, a QTL with large effects may turn out to be caused by several linked QTLs each with a small effect. Third, most QTLs have mild phenotypic effects, which make it more difficult to spot a candidate mutation compared with mutations underlying monogenic disorders that often disrupt protein function or drastically reduce gene expression. Furthermore, QTLs may often be due to regulatory mutations that are much more difficult to find and functionally characterize compared with mutations in coding sequence.

The poor resolution in QTL mapping can be overcome by progeny testing and marker segregation analysis, which makes it possible to deduce the QTL status of the parental haplotypes with great confidence. This leads to a collection of haplotypes with known QTL alleles that in turn can be used for high-resolution mapping and sequencing. This may eventually lead to the causative mutation, at least in those favorable situations when the QTL is caused by a single mutation. This can be achieved by QTL analysis of extended pedigrees in commercial populations (Blott *et al*., 2002; Grisart *et al*., 2002; Winter *et al*., 2002). Available data also suggest that the same favorable QTL allele may be found in different breeds since there is often some gene flow between breeds (Van Laere *et al*., 2003), which should facilitate high-resolution QTL mapping. There is, therefore, a considerable interest to develop statistical methodology that can combine linkage and linkage disequilibrium mapping (Farnir *et al*., 2002; Meuwissen and Goddard, 2000; Meuwissen and Goddard, 2001; Perez-Enciso, 2003).

QTL mapping in F_2 intercrosses also suffer from a poor resolution in QTL assignments. This can be remediated by selective back-crossing or by the generation of advanced intercross lines (AIL) (Darvasi, 1998; Darvasi and Soller, 1995). Selective back-crossing first involves the identification of putative breeding sires that carry informative recombinant haplotypes. Second, progeny testings are done to determine the QTL status for the recombinant haplotypes (Marklund *et al*., 1999). The maintenance of an AIL allows the accumulation of recombinants that break up the strong linkage disequilibrium generated by cross-breeding. An AIL has the merit compared with selective back-crossing that it generates a material suitable for high-resolution QTL mapping for all the QTLs detected in the intercross.

Like in all other species, there are few QTLs in farm animals for which the underlying causative mutation have been identified. There are a couple of

examples where a mutation determining a monogenic trait also acts as a QTL for a multifactorial trait (Table 3). A missense mutation in the gene for the ryanodine receptor (*RYR1*) predisposes to malignant hyperthermia but also affects lean meat content in the pig (Fujii *et al*., 1991). Similarly, a missense mutation in the gene for the muscle-specific isoform of the regulatory $\gamma 3$ chain of AMP-activated protein kinase (*PRKAG3*) causes excess glycogen content in skeletal muscle and has an effect on lean meat content in the pig (Milan *et al*., 2000). Both these mutations have increased in frequency as a consequence of the strong selection for lean pigs, but diagnostic DNA tests have now been used to reduce their frequency in order to avoid the negative pleiotropic effects on other traits. A gene duplication and a splice mutation in the porcine *KIT* gene causes dominant white color and have pleiotropic effects on hematopoiesis (Marklund *et al*., 1998). More recently, it has been shown that the *PMEL17* locus in chicken both determines dominant white color and influences the risk of becoming a victim for feather pecking in the F_2 generation of a red jungle fowl/White Leghorn intercross (Keeling *et al*., 2004; Kerje *et al*., 2004).

Three mutations underlying QTLs in cattle and pig have been identified by a positional candidate cloning approach; in all three cases, an IBD approach facilitated the identification of the causative mutation. Missense mutations were detected in the genes for diacylglycerol transferase (*DGAT*) and the growth hormone receptor (*GHR*) as causing two major milk-production QTLs on chromosome 14 and 20, respectively (Blott *et al*., 2002; Grisart *et al*., 2002; Winter *et al*., 2002). Subsequent functional studies provided strong support for that the K232A mutation in *DGAT* in fact is causing the QTL effect (Grisart *et al*., 2004). A paternally expressed QTL with major effects on muscle mass, size of the heart, and back-fat thickness is located at the distal end of pig chromosome 2p (Jeon *et al*., 1999; Nezer *et al*., 1999). The QTL has been found in several intercrosses, including a wild boar/domestic pig intercross in which the QTL allele inherited from the domestic pig was associated with higher muscle mass and reduced back-fat thickness. Sequence analysis of ~28 kb of genomic DNA around the *IGF2* locus using 15 chromosomes with known QTL status led to the identification of the causative mutation in the form of a single point mutation in the middle of intron 3 in *IGF2* (Van Laere *et al*., 2003). The mutation occurs in an evolutionary conserved CpG island and in a 16-bp fragment that is completely conserved among eight mammalian species. Functional analysis revealed that the mutation disrupts the interaction with a nuclear factor, most likely a repressor, and leads to an upregulation of *IGF2* expression in postnatal skeletal and cardiac muscle but not in fetal muscle or in liver. The mutation has gone through a selective sweep in many commercial populations selected for lean meat content (Van Laere *et al*., 2003).

As high-density marker maps are developed and the cost for SNP typing is going down, it will be possible to carry out genome-wide association analysis. The number of markers required will vary from species to species and from population to population depending on the degree of linkage disequilibrium in the target population, but the number will be on the order of 10 000 loci or more. Furthermore, as the cost for DNA sequencing is going down, we will not only generate complete genome sequences for the farm animals but we will also be able to resequence individuals representing different breeds. Such comparative

sequence analysis should reveal footprints of the selection that has taken place during domestication and selective breeding (Andersson and Georges, 2004). The expected pattern is that a haplotype carrying one or more favorable mutations will be fixed or close to fixation in certain selected lines. Such data combined with genetic data from linkage or association analysis will be a gold mine for studying genotype–phenotype relationships.

1. Introduction

With the completion of the mouse and human genome sequences, a major challenge is the functional characterization of every gene within the mammalian genome and the identification of gene products and their molecular interaction network. The mouse offers many advantages for the use of genetics to the study of human biology and disease. Its development, body plan, physiology, behavior, and diseases (*see* Article 12, **Haplotype mapping**, Volume 3) have much in common, which is based on the fact that 99% of the mouse genes have a human ortholog. The investigation of gene function using mouse models is built on many years of technology development. A variety of mouse mutagenesis technologies, either gene- or phenotype-driven, are used as systematic approaches. The availability of the mouse genome sequences (*see* Article 47, **The mouse genome sequence**, Volume 3) supports gene-driven approaches such as gene-trap and targeted mutagenesis in embryonic stem (ES) cells, allowing an efficiency and precision of gene disruption unmatched among other mammals. Furthermore, chemical and transposon mutagenesis of the mouse genome allows to perform phenotype-driven screens for the unbiased identification of phenotype–genotype correlations involved in models of human disease. Taken together, the application of these approaches have already resulted in a worldwide collection of several thousand mouse mutants and will form the basis to generate mutations in every gene and to decipher their physiological function. In the following sections, we present a comprehensive review of gene- and phenotype-driven mutagenesis strategies applied to the mouse genome. Besides a summary of the basic principles of each approach, we emphasize on the latest and future developments of mouse mutagenesis.

2. Gene-trap mutagenesis

Gene-trap mutagenesis is based on the random integration of a gene-trap vector across the genome of ES cells and the disruption of coding sequences of genes through vector-specific elements. Gene-trap vectors simultaneously mutate a gene at the site of insertion, provide a sequence tag for the rapid identification of the disrupted gene, and mimic the expression of the tagged gene by a reporter gene. Since a single DNA or retroviral vector can be used to hit a large number of genes, gene trapping is a high-throughput insertional mutagenesis approach that enables to establish libraries of mutant ES cell clones rapidly and at low costs (Gossler *et al*., 1989; Friedrich *et al*., 1991; Skarnes *et al*., 1992; Wurst *et al*., 1995; Zambrowicz *et al*., 1998; Wiles *et al*., 2000; Hansen *et al*., 2003). The resulting databases of mutant genes provide the basis for the establishment of mutant mouse strains through germ-line chimeras raised from selected ES cell clones.

Typical gene-trap vectors are promoterless and contain a reporter–selector cassette that functions by generating a fusion transcript with the endogenous gene (Figure 1a). The most widely used βgeo cassette contains an ATG-less hybrid-coding region for the β-galactosidase reporter and the neomycin phosphotransferase selection marker (Friedrich *et al*., 1991). The inclusion of a splice acceptor element (SA) upstream of βgeo leads to the generation of a fusion transcript upon vector integration into an intron of a transcribed gene in ES cells. The fusion transcript will ideally be prematurely terminated at a polyadenylation signal sequence (polyA) placed downstream of the βgeo element. In case that the translational reading frames of the trapped transcript and the βgeo cassette are in line, a fusion protein is produced that confers resistance of the ES cell clone to the neomycin analog G418. To identify genes independent of reading frames, an internal ribosomal entry site (IRES) can be placed between SA and a βgeo version that includes an ATG start codon.

Upon introduction of a gene-trap vector into ES cells by electroporation or retroviral infection, the population is selected for G418 resistance such that only ES colonies harboring a productive vector integration into an active gene are able to survive. This stringent selection scheme is the basis for the high efficiency of gene-trapping technology since each resistant ES cell clone represents an independent integration event into a unique gene (Stanford *et al*., 2001; Floss and Wurst, 2002). However, gene-trap vectors that rely on the use of a splice acceptor element to express a resistance marker can identify all genes sufficiently transcribed in ES cells and that contain introns but not those genes that are not expressed in ES cells. To further extend the application of gene trapping to all genes, independent of their expression status in ES cells, poly(A)-trap vectors have been developed. These vectors contain a promoter-driven resistance gene followed by a splice donor element (SD) without a poly(A) sequence (Niwa *et al*., 1993; Zambrowicz *et al*., 1998). Thus, drug resistance is only obtained after successful vector integration into an endogenous gene and the capture of its poly(A) signal by the vector-derived transcript.

ES cells are commonly used as the substrate for insertional mutagenesis through gene-trap vectors. Recently, an alternative strategy has been developed that relies on the *Sleeping Beauty* transposable element as germ-line insertional mutagen (Izsvak

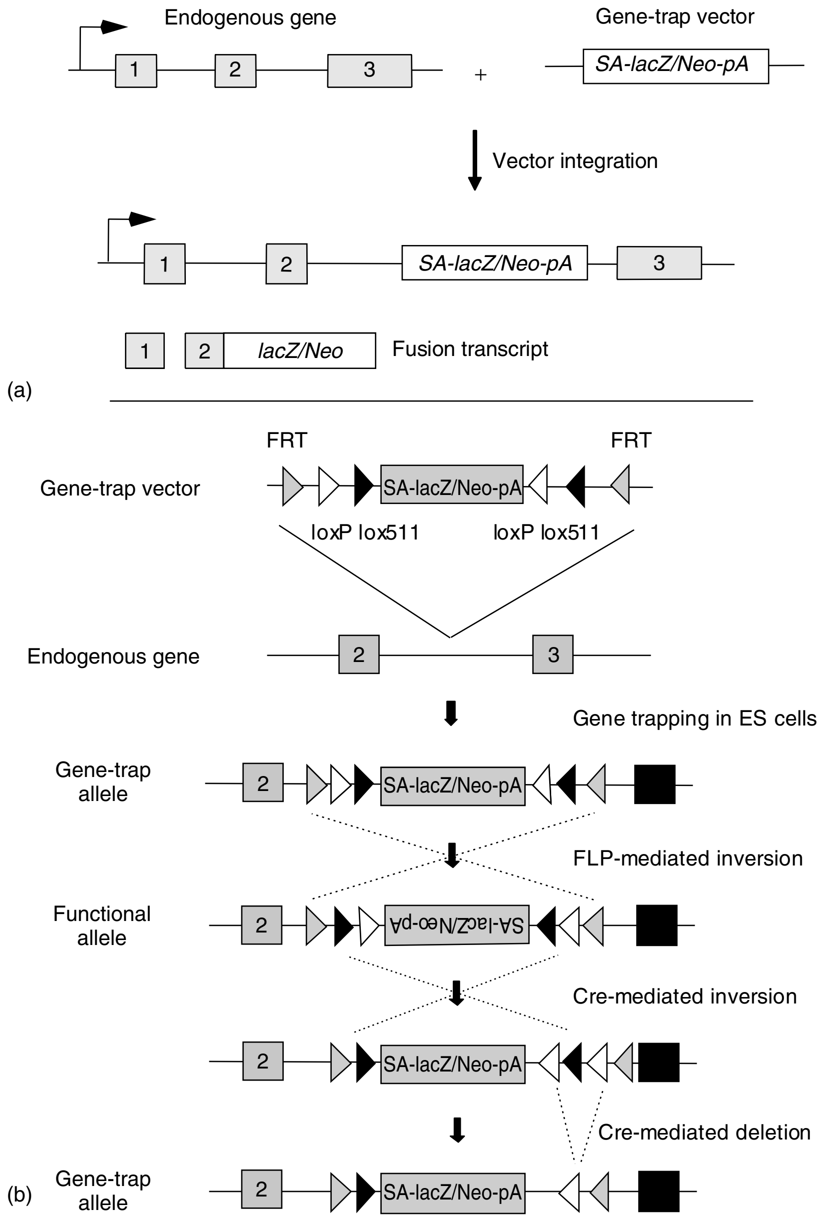

Figure 1 Gene-trap mutagenesis. (a) integration of a standard gene-trap vector into an endogenous gene. SA – splice acceptor sequence, pA – poly(A) sequence. (b) Integration of a conditional gene-trap vector into an endogenous gene. The initial gene-trap allele can be converted into a functional allele by FLP-mediated inversion of the mutagenic gene-trap cassette in ES cells or FLP deleter mice. This cassette can be irreversibly reinverted through Cre-mediated recombination in ES cells or Cre transgenic mice

et al., 2000; Horie *et al*., 2003; Carlson *et al*., 2003). In this in vivo approach, doubly transgenic mice harbor a transposase transgene and a transposon poly(A) gene-trap vector that can be mobilized by transposition. For this purpose, the mutagenic cassette of a poly(A) gene-trap vector is flanked by a pair of transposon terminal inverted repeats that contain transposase binding sites. This element is excised in the male germline of doubly transgenic mice and reintegrates into new genomic locations. Upon the outcross of transgenic males to wild-type females, the offspring contains new transposon insertions that are found at a frequency of ~2 per male gamete. The analysis of several hundred integration sites revealed that about 30% of transposition events occur locally clustered within 3 Mb near the donor site, while the other events are widely distributed across various chromosomes (Horie *et al*., 2003; Carlson *et al*., 2003). Thus, the in vivo transposition of gene-trap vectors can be applied to region-specific and genome-wide mutagenesis.

In addition to broadly acting gene and poly(A) traps, specific classes of proteins can be trapped with modified vectors. A secretory trap vector, designed to capture genes for secreted or membrane proteins expressed in ES cells, contains a membrane spanning domain fused to the amino terminus of the βgeo reporter–selector cassette (Skarnes *et al*., 1995; Mitchell *et al*., 2001). Thereby, the activation of βgeo depends on the production of fusion proteins that incorporate an N-terminal signal sequence or a transmembrane domain from the gene at the insertion site. To further increase the versatility of gene-trap mutagenesis, vectors were developed that include recognition sequences for the site-specific DNA recombinase Cre (Araki *et al*., 1999; Hardouin and Nagy, 2000). These vectors enable recombinase-assisted postinsertional modifications at the gene-trap locus in ES cells to drive the expression of any foreign cDNA from the specific promoter of the trapped gene.

The currently employed gene-trap vectors irreversibly modify the endogenous target genes, comparable to germ-line null mutations created by gene targeting in ES cells (Figure 1a). To avoid the potential embryonic lethality of targeted germ-line mutants, a scheme for conditional gene targeting has been introduced that enables to restrict gene inactivation to specific cell types by the use of the Cre/loxP recombination system (see Section (4)). The upcoming generation of gene-trap vectors is designed to combine the advantages of gene-trap and conditional mutagenesis by the development of conditional gene-trap vectors (Melchner and Stewart, 2004) (Figure 1b). These vectors rely on a reporter–selector cassette like βgeo that can be independently inverted by the site-specific recombinases Cre or FLP. For this purpose, the cassette can be flanked by a pair of FRT sites that allows to invert the cassette by FLP-mediated recombination upon the usual establishment of a gene-trap integration into an expressed gene. In its original sense, orientation of the cassette disrupts the expression of the trapped gene, whereas the inverted cassette should be nonmutagenic and enable gene expression at wild-type levels. In addition, the cassette must be flanked by a pair of wild-type and mutant loxP sites in a specific order and orientation such that an irreversible inversion is mediated by Cre recombinase (FLEx strategy; Schnütgen *et al*., 2003). When mice that harbor such a silent gene-trap cassette are crossed to a transgenic strain with tissue-specific expression of Cre, the gene trap should be reactivated in vivo and lead to the conditional disruption of the target gene.

The analysis of more than 5000 gene-trap events by Hansen *et al*. (2003) revealed that gene-trap insertions are dispersed throughout the genome and occur more frequently in chromosomes with a high density of genes. All functional classes of mammalian genes are amenable to gene trapping. However, the integration of gene-trap vectors is not entirely random and several preferred integration sites (hot spots), some of which occur many times, have been observed. About half of these hot spots are associated with the use of specific gene-trap vectors, while the other half occurs independent of the specific vector design. With the increasing size of a gene-trap library, the rate of trapping new genes is not linear but declines since multiple integrations accumulate and the pool of new trappable genes decreases. About 700 genes were trapped within a pool of the first 1600 integrations of a gene-trap vector (Hansen *et al*., 2003), while only 1 new gene was added every 35 tags in a library comprising over 100 000 insertions of a poly(A)-trap vector (Skarnes *et al*., 2004). Considering that over half of the multiple integrations are vector specific, the most effective way to saturate the genome with gene-trap insertions is the use of a variety of gene-trap vectors.

Ideally, the integration of a gene-trap vector leads to the functional knockout of the trapped endogenous gene. The mutagenicity of a given vector in respect of interrupting the endogenous transcript depends on the relative strength of the splice acceptor and poly(A) sites flanking the reporter–selector element. In addition, the mutagenicity of gene-trap vectors is likely also determined by their integration position within a trapped gene. The majority of retroviral gene-trap insertions occurs in the 5′-half of genes, whereas insertions of plasmid vectors are distributed more evenly over the entire gene-coding regions (Hansen *et al*., 2003). In some cases, the combination of a specific insertion site and gene-trap vector is not entirely effective such that the vector sequence can be excised from the endogenous transcript as part of the intron into which the integration has occurred. In this case, wild-type gene product is produced to some extent and may lead to a hypomorphic mutation. In a side-by-side comparison of 11 gene-trap mutants with targeted mutants affecting the same genes, all but one phenocopied the targeted mutants, while one strain showed a partial loss-of-function (Mitchell *et al*., 2001). The overall analysis of homozygous mouse mutants derived from gene-trap ES cell clones revealed that 60% of the strains exhibit obvious phenotypes and 30% of these phenotypes lead to embryonic lethality (Stanford *et al*., 2001; Hansen *et al*., 2003). This frequency is comparable with mutants generated by gene targeting, indicating that most gene-trap insertions result in null alleles.

Gene-trap mutagenesis in ES cells is a large-scale effort that cannot be completed by a single group but requires cooperation within the research community. Six gene-trap screens run by academic research centers across Europe and North America are combined in the International Gene Trap Consortium (IGTC; Table 1). The IGTC collection of gene-trap ES cell clones includes 27 000 independent insertions, which represent a 32% coverage of all mouse genes (Skarnes *et al*., 2004). The IGTC gene-trap ES cell clones are freely available to academic scientists, and the sequence tags of all insertions are mapped on the Ensembl mouse genome server (Table 1), providing a direct link to any gene of interest. A parallel effort was initiated by the biotechnology company Lexicon Genetics that developed a large library of gene-trap clones (OmniBank; Zambrowicz *et al*., 1998). This collection

of 200 000 sequence tags deposited in GenBank achieves close to 60% coverage of the mouse genome (Skarnes *et al*., 2004). The two efforts together presently cover nearly two-thirds of the mouse genome such that gene trapping has proven to be the most effective strategy to mutate a substantial fraction of all mouse genes. Therefore, gene trapping is the first choice of the European- and US-based initiatives that plan the complete mutagenesis of all mouse genes (Auwerx *et al*., 2004; Austin *et al*., 2004).

3. Gene-targeting mutagenesis

Gene targeting allows the introduction of predesigned, site-specific modifications into the mouse genome (Capecchi, 1989). It has been extensively used in the past decade for the preplanned disruption of genes in the murine germline, resulting in mutant strains referred to as *knockout mice*. Gene inactivation is achieved through the insertion of a selectable marker into an exon of the target gene or the replacement of one or more exons.

The mutant allele is initially assembled in a specifically designed gene-targeting vector such that the selectable marker is flanked at both sides with genomic segments of the target gene that serve as homology regions to initiate homologous recombination. The frequency of homologous recombination increases with the length of these homology arms. Usually, arms with a combined length of 10–15 kb are cloned into standard, high-copy plasmid vectors that accommodate up to 20 kb of foreign DNA. To select against random vector integrations, a negative selectable marker, such as the *Herpes simplex* thymidine kinase or diphteria toxin gene, can be included at one end of the targeting vector. Upon electroporation of such a vector into ES cells and the selection of stable integrants, clones that

underwent a homologous recombination event can be identified through the analysis of genomic DNA using a PCR or Southern blot strategy. Using such standard gene-targeting vectors, the frequency of homologous recombination falls into the range of 0.1–10% of stable transfected ES cell clones. This rate depends on the length of the vector homology region, the degree of sequence identity of this region with the genomic DNA of the ES cell line, and likely on the differential accessibility of individual genomic loci to homologous recombination. Optimal rates are achieved with longer homology regions and by the use of genomic fragments that exhibit sequence identity to the genome of the ES cell line, that is, both should be isogenic and derived from the same inbred mouse strain. Upon the isolation of recombinant ES cell clones, modified ES cells are injected into blastocysts to transmit the mutant allele through the germline of chimeras and to establish a mutant strain. Through interbreeding of heterozygous mutants, homozygotes are obtained that can be used for phenotype analysis. Most knockout strains have been generated one by one through the standard scheme described above; an approach that typically requires 1–2 years of hands-on work for vector construction, ES cell culture, and mouse breeding. Working protocols and technical details of the gene-targeting technology have been compiled in a recent manual (Nagy *et al*., 2003).

Since the first demonstration of homologous recombination in ES cells by Thomas and Capecchi in 1987, gene targeting has been successfully used to generate more than 2500 knockout mouse strains. Thus, almost 10% of the mouse genome is presently covered by targeted mutations. While all published mutants and their phenotypes are recorded in databases (Table 1), the availability and distribution of these strains becomes increasingly difficult. The Jackson Laboratories, as the largest distribution center, presently holds about 350 targeted mutants (Table 1).

Using the "classical" gene-targeting approach described above, germ-line mutants are obtained that harbor the knockout mutation in all cells throughout development. This strategy identifies the first essential function of a gene during ontogeny. If the gene product fulfills an important role in development, its inactivation can lead to embryonic lethality, precluding further analysis in adult mice. In the mean, about 30% of all knockout mouse strains exhibit an embryonic lethal phenotype; for specific classes of genes, for example, those regulating angiogenesis, this rate can reach 100%. To avoid embryonic lethality and to study gene function only in specific cell types, Gu *et al*. (1994) introduced a modified, conditional gene-targeting scheme that allows to restrict gene inactivation to specific cell types or developmental stages (Figure 2). In a conditional mutant gene, inactivation is achieved by the insertion of two 34-bp recognition (loxP) sites of the site-specific DNA recombinase Cre into introns of the target gene such that recombination results in the deletion of loxP-flanked exons. Conditional mutants initially require the generation of two mouse strains: one strain harboring a loxP-flanked gene segment obtained by gene targeting in ES cells (Figure 2a) and a second, transgenic strain expressing Cre recombinase in one or several cell types. The conditional mutant is generated by crossing these two strains such that target gene inactivation occurs in a spatial and temporal restricted manner, according to the pattern of recombinase expression in the Cre transgenic strain (Torres and Kühn, 1997; Nagy *et al*., 2003; Figure 2b). In addition, the loxP-modified strain can be converted into a conventional germ-line mutant through the cross to a Cre

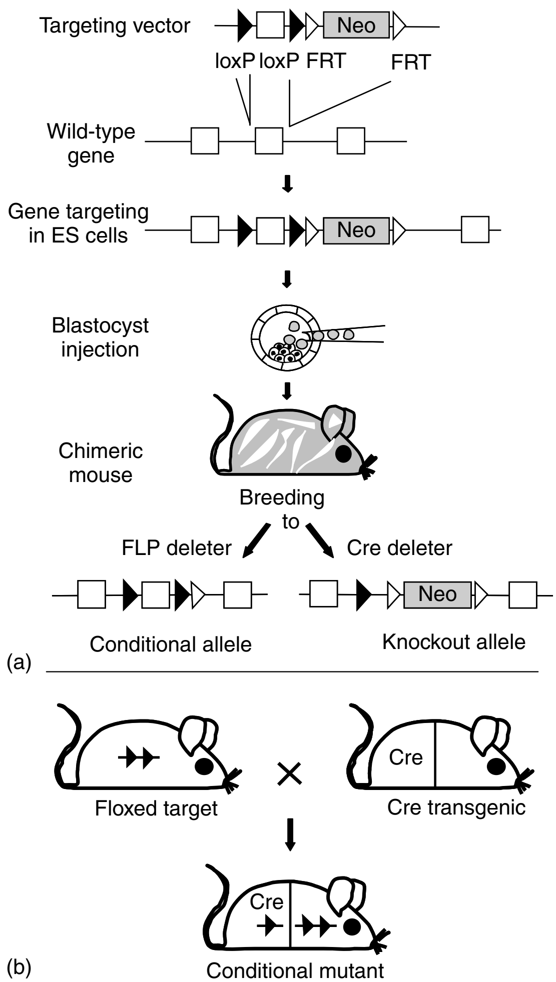

Figure 2 Conditional gene targeting. (a) A target gene exon is flanked by loxP sites, the selection marker (neo) is flanked by FRT sites. Upon gene targeting in ES cells and germ-line transmission, the conditional allele is generated upon deletion of the selection marker by a cross to FLP deleter mice. A cross to Cre deleter mice generates a germ-line knockout allele. (b) A mouse carrying a loxP-flanked (floxed) target gene is crossed to a transgenic mouse expressing Cre recombinase in specific cell types (Cre is restricted to the left-hand portion). In the resultant double transgenic mouse (bottom), recombination of the floxed target is restricted to cells expressing Cre. Filled triangles represent the loxP sites

deleter strain that expresses recombinase in germ cells (Figure 2a). Both types of mutants are often generated side by side from the same ES cell clone to investigate gene function during embryonic development and in the adult animal.

Conditional mutants have been used to address various biological questions that could not be resolved with germ-line mutants, often because a null allele results in an embryonic or neonatal lethal phenotype. For this purpose, more than 100

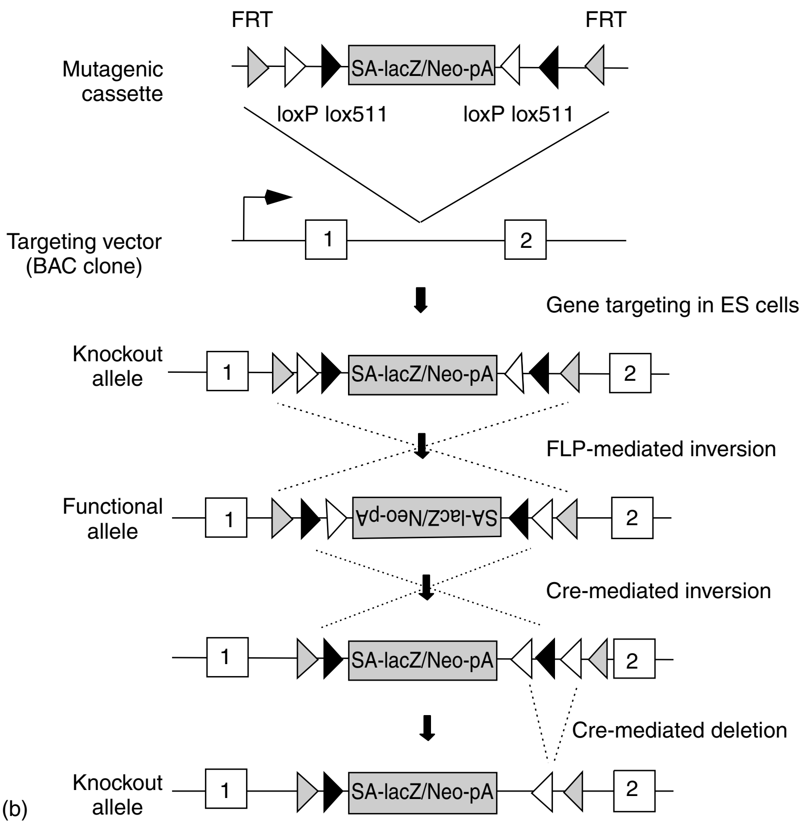
Cre transgenic strains with tissue-specific recombinase expression have been published that cover many cell types for which a specific promoter region is available (Table 1; Nagy *et al*., 2001); about 30 of these strains are available from the Jackson Laboratory. The characteristics of a given line can be identified by crossing to a Cre reporter strain that activates a reporter gene upon Cre-mediated deletion of a loxP-flanked transcriptional stop cassette (Soriano, 1999). Most Cre transgenic strains express recombinase from a constitutively active promoter, starting with the activation of the promoter region during development.

A smaller number of Cre mice allows to induce Cre activity in one or more cell types upon the administration of a small molecule inducer (Lewandoski, 2001). Transcriptional control of Cre has been achieved by the tetracycline-inducible gene expression system in transgenic mice using doxycycline as inducer (Utomo *et al*., 1999). This system requires the independent introduction of two genes coding for a doxycycline-regulated transactivator protein and for Cre recombinase, and thus numerous transgenic lines must be crossed and tested to identify the strains in which both genes are optimally regulated. Posttranslational control of Cre activity has been achieved by the expression of fusion proteins of Cre with mutant ligand-binding domains of the estrogen or progesterone receptor (Feil *et al*., 1997; Kellendonk *et al*., 1999; Branda and Dymecki, 2004). These ligand-binding domains are unresponsive to natural steroids but can be activated in mice by the administration of synthetic steroid antagonists.

Conditional alleles have been generated for more than 100 genes that lead to embryonic lethality in case of a germ-line knockout (Kwan, 2002). The generation of conditional alleles involves the same technology as the production of germ-line knockouts but the construction of gene-targeting vectors and mouse breedings require more time and efforts. For the construction of a conditional gene-targeting vector, a selection marker and a loxP site are inserted into one intron of the target gene while a second loxP sequence is placed into another intron. Upon homologous recombination, the selection marker gene is usually removed from the targeted allele to avoid its potential interference with the expression of the loxP-modified gene. For this purpose, the selection marker can be flanked with FLP recombinase recognition (FRT) sites and deleted from the genome by a cross of mice harboring the targeted allele to a transgenic strain that expresses FLP in germ cells (Rodriguez *et al*., 2000; Figure 2a). Upon removal of the selection marker, the loxP-flanked allele can be bred to homozygosity together with the required Cre transgene to obtain conditional mutants for phenotype analysis (Figure 2b).

Owing to the higher efforts required for the generation of conditional mutants, this technology has been mostly applied to genes that possess important functions in the adult but exhibit an embryonic lethal knockout phenotype. Besides the avoidance of embryonic lethality, a conditional mutant can reveal information about the function of a widely expressed gene in different tissues by combination with various Cre lines.

In addition to the use of Cre/loxP for gene inactivation, site-specific recombination has been applied to achieve other types of genome manipulation in ES cells or mice. These include the generation of large chromosomal deletions or inversions, of chromosomal translocations, gene replacement, recombinase-mediated cassette exchange, and the inversion of gene segments (Branda and Dymecki, 2004).



Gene targeting, in its first decade, has largely progressed in a one-by-one manner by the contributions of a large number of laboratories; for each mutant, 2–3 years of work are required for vector construction, ES cell culture, mouse breeding, and analysis. Thus, gene targeting is presently a low-throughput technology, in contrast to gene trapping that generates insertional mutations in ES cells at much larger numbers and with less effort because a single, generic vector can be used to mutagenize any gene. However, with the recent advance in technology, as described below, it is possible to produce targeted mutants faster and at larger scale.

The first advance is the development of novel DNA engineering strategies that rely on homologous recombination in bacteria, utilizing the phage-derived recombination protein pairs RecE/RecT (ET cloning; Muyrers *et al*., 2001) or Redα/Redβ (Recombineering; Copeland *et al*., 2001). These recombination functions are either carried on plasmids or have been inserted into the bacterial genome. For gene-targeting purposes, this technology enables to manipulate large genomic sequences cloned into BAC vectors without the use of restriction enzymes or ligation reactions (Angrand *et al*., 1999). Since the whole mouse genome is available in the form of sequenced BAC clones, all genes are readily accessible to these methods.

First, it is possible to subclone genomic fragments from BAC vectors into standard cloning plasmids as a basis of gene-targeting vector construction. In a second ET/recombineering step, a selection cassette that functions in bacteria as well as ES cells can be inserted at a preselected site to produce a vector for standard knockout alleles. This can be combined with a third step to introduce a loxP sequence at a distant site for the construction of conditional gene-targeting vectors (Muyrers *et al*., 2001; Liu *et al*., 2003). Thereby, starting from BAC clones and oligonucleotides, ET cloning/recombineering allows to construct gene-targeting vectors within a few weeks.

The second advance builds on these BAC manipulation methods and further simplifies their handling such that complete, modified BAC clones are directly used as gene-targeting vectors. Owing to the size of the vector homology arms of 100–200 kb, it is not practicable to identify recombinant ES cell clones by standard Southern blotting such that two alternative strategies were developed. The first, "Velocigene" procedure (Valenzuela *et al*., 2003), takes advantage of the fact that only one copy of the wild-type target gene remains in homologous recombined ES cells, while random BAC vector integrants retain both wild-type copies. To test whether ES cell clones harbor a random or targeted vector integration, their genomic DNA is assayed by quantitative PCR to determine the copy number of the wild-type allele in comparison to an internal standard. In the second approach (Yang and Seed, 2003), all ES cell clones are first screened for the presence of a random integration using a vector-specific PCR. The remaining clones are assayed by fluorescent in situ hybridization (FISH) for the presence of only two hybridization signals indicating homologous recombinants. The use of BAC clones considerably simplifies the construction of gene-targeting vectors. Furthermore, BAC-targeting vectors are reported to result in high frequencies of homologous recombination in ES cells (Valenzuela *et al*., 2003), even if the vector arms and the ES cell line are nonisogenic, that is, derived from different inbred strains.

It can be anticipated that the next technical step toward the streamlined production of targeted mutants will follow shortly, with the development of generic

(b)

Figure 3 Generic conditional gene targeting. A conditional mutagenic cassette, inserted by bacterial homologous recombination into a generic site (intron 1) of genomic BAC clones, serves as a gene-targeting vector in ES cells. The initial knockout allele can be converted into a functional allele by FLP-mediated inversion of the mutagenic cassette in ES cells or FLP deleter mice. This cassette can be irreversibly reinverted through Cre-mediated inversion and deletion in ES cells or Cre transgenic mice

conditional gene-targeting vectors. These vectors will combine BAC clones as backbone of targeting vectors with an invertable gene disruption cassette, as used for conditional gene-trap mutagenesis (Figure 3). The irreversible inversion of a mutagenic cassette through Cre recombinase can be achieved by the FLEx approach (Schnütgen *et al*., 2003) that combines wild-type and mutant lox sites with a Cre-mediated inversion and deletion step. In addition, the cassette can be (reversibly) inverted by FLP/FRT-mediated recombination such that the initial knockout configuration is converted into a conditional allele in ES cells or FLP deleter mice (Figure 3). Such a cassette could be inserted in a generic manner into the first intron of any target gene and would allow to produce conditional targeting vectors by a single ET cloning step. This technology may contribute to cover the whole mouse genome by a combination of gene-trap and targeted mutagenesis, as planned by the European mouse mutagenesis program (Auwerx *et al*., 2004).

4. ENU mutagenesis

ENU (ethylnitrosourea) mutagenesis is a phenotype-driven approach, whereby large numbers of mutations are induced at random and new mutants are identified through specific phenotype screens (Justice, 2000; Brown and Balling, 2001; Brown and Hardisty, 2003). Since no prior assumption is made about the underlying genes, ENU mutagenesis represents an unbiased way for the identification of genes and genetic pathways involved in biological processes.

At the beginning of a mouse ENU mutagenesis screen, high doses of ENU are repeatedly administrated to a group of males. Upon a transient phase of infertility, the testes of ENU-treated animals are repopulated by gametes derived from mutagenized stem cells. The chemical mutagen ENU generates point mutations by the transfer of its ethyl group on oxygen or nitrogen residues of DNA, resulting in mispairing and base-pair substitution upon DNA replication. The highest ENU-induced mutation rates occur in premeiotic spermatogonial stem cells. Given a specific locus mutation rate of around 10^{-3}, the likelihood curves indicate that one has to screen around 2000–3000 gametes to have a 90% or higher chance of observing one mutation. The mutagenized males are bred to wild-type females and progeny of the resulting G1 generation can be directly screened for the presence of novel phenotypes caused by dominant mutations (Soewarto *et al*., 2003). To identify recessive mutations, G1 males and females are crossed in defined breeding pairs to produce a second, G2 generation. G2 females are then backcrossed to their father to obtain a third (G3) generation in which recessive mutations, inherited by the father, can become homozygous (Figure 4). G3 progeny (around 20–30 in total) from several litters derived from each G1 male are screened for the biological parameters of interest to score for individuals that exhibit a mutant phenotype. Upon the identification of variant individuals, breeding allows to establish mutant strains that are maintained as breeding colonies for further analysis. Confirmed mutant strains that exhibit similar phenotypes may be based on independent mutations in the same gene; alternatively, different genes with similar functions could be affected. The number of genes affected in a group of mutants can be estimated by complementation analysis through the cross of different mutants.

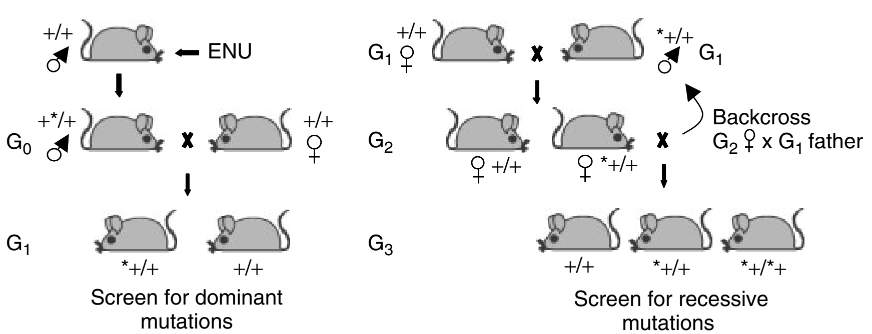


Figure 4 ENU mutagenesis. Breeding scheme to identify dominant and recessive mutants induced by ENU mutagenesis

To identify the mutant gene and the underlying mutation at the molecular level, a generic low-resolution mapping approach enables the rapid assignment of a mutation to a particular chromosomal segment (*see* Article 9, **Genome mapping overview**, Volume 3 and Article 15, **Linkage mapping**, Volume 3). The initial step of genetic mapping requires that mutants on the specific inbred background be outcrossed with a second mapping strain, resulting in F1 hybrid progeny that acquires one set of chromosomes from each of the parental strains. The mapping strain should exhibit numerous polymorphic markers interspersed throughout the genome. Meiotic recombination in F1 mice shuffles chromosomal segments and allows to identify in the next generation markers that cosegregate with the mutant phenotype and are closely linked to the mutant locus (linkage analysis). For the mapping of dominant mutations, F1 mice are further backcrossed to the mapping strain; to map recessive mutations, F1 mice are intercrossed in brother–sister matings, yielding progeny of which 25% are homozygous for the mutation. As an alternative to natural matings, large numbers of offspring can be produced from a single male through in vitro fertilization (IVF) of oocytes using fresh or frozen sperm (Thornton *et al*., 1999). The offspring of these matings are then analyzed for the linkage of the mutant phenotype with specific genetic markers. For this purpose, polymorphic genetic markers such as simple sequence length polymorphisms (SSLPs; microsatellites; Witmer *et al*., 2003) and single nucleotide polymorphisms (SNPs; Lindblad-Toh *et al*., 2000) are used that are anchored on the genome and can be analyzed by PCR amplification from genomic DNA. Provided that a sufficient number of mice is available, this mapping approach often allows to assign mutations to a region of less than 1 Mb of the genome, corresponding to 5–10 genes that can be considered as candidates for the mutant gene. In consideration of the results of biological analyses obtained from the mutant and computational prediction of gene functions, a likely candidate gene can be often defined. Finally, this candidate gene must be analyzed at the molecular level by sequencing of cDNA or PCR-amplified exon regions from mutant and control mice.

The analysis of 62 germ-line mutations derived from 24 genes revealed that ENU preferentially modifies A/T base pairs and mainly leads to T/A transversions and G/C transitions (Justice *et al*., 1999). Translated into protein products, 64% of these changes result in missense mutations, 10% lead to a premature stop codon, and 26% affect mRNA splicing. In most cases, the affected proteins exhibit a partial or complete loss-of-function but gain-of-function mutations, for example, by the loss of an inhibitory domain of a tumor suppressor gene (Moser *et al*., 1995), have been also described. An advantage of ENU mutagenesis is that it can evoke a range of mutations within a single gene that may affect protein function in different ways. Such allelic series can provide a fine structure dissection of protein function.

Since ENU mutagenesis is a phenotype-driven approach, mutant isolation relies on the spectrum and quality of available phenotype assays. The screen of a large number of animals further requires that first-line detection assays are broad, simple, and inexpensive. Visible phenotypes that affect the eye, coat, or size are most simple to detect. Standard test for reflexes, sight or hearing loss, balance, and coordination can be used to screen for motor and sensory organ phenotypes. X-ray analysis enables to examine skeletal and soft tissue development. Clinical tests performed on mouse blood can yield phenotypes relevant to hematological and immunological

disease, while clinical chemistry on serum components can diagnose multiple organ system anomalies. The development of new approaches in phenotyping and the standardization of primary and secondary phenotyping protocols for all body systems in the mouse is the subject of a dedicated research programme (EUMORPHIA; Table 1). Some of the participating phenotyping centers, like the Mouse Clinical Institute and the German Mouse Clinic (Table 1), also provide service units for the characterization of targeted and gene-trap mutants.

The results of two genome-wide screens for dominant mutations of the United Kingdom and German ENU mutagenesis programmes have been recently reported (Nolan *et al*., 2000; Hrabe de Angelis *et al*., 2000; Justice, 2000). Both groups applied a range of phenotype screens to identify mutants relevant to human disease by assessment of visible phenotypes, the detection of sensory, neuromuscular, and neurological defects by a stepwise assessment of many parameters (SHIRPA protocol) or hematological and clinical chemistry assays. From screening 40 000 mice together, these groups have isolated around 1000 new mutations. Mutants were found for any phenotypic area of interest, and the overall rate of recovery of dominant mutations was in the range of 2%. About 10 large-scale ENU mutagenesis programmes are maintained worldwide, each with a specific biological focus on neurological, behavioral, morphological, developmental, or immunological phenotypes (Brown and Balling, 2001). These ongoing efforts, mostly genome-wide screens for recessive mutations, have already yielded important models of human disease (Vreugde *et al*., 2002; Toye *et al*., 2004) and will further significantly contribute to draw a functional map of the genome.

Besides the mutagenesis of the wild-type genome, ENU can be further employed to screen for modifier genes (Nadeau, 2001) on the genetic background of an established mutant or transgenic strain that exhibits a specific phenotype. Such modifier screens are used to search for additional members of a genetic pathway that influence a given phenotype in positive or negative manner, resulting in the isolation of suppressor or enhancer mutants. This and other sophisticated screening procedures are routinely used in fruit flies (St Johnston, 2002; *see also* Article 42, **Systematic mutagenesis of nonmammalian model species**, Volume 3) to identify modifiers of preexisting genetic defects and may provide a paradigm for the future development of ENU mutagenesis screens in the mouse. The results of the first suppressor screen on the background of a targeted mouse mutant have been recently reported (Carpinelli *et al*., 2004).

A new opportunity to capitalize on chemical mutagenesis in the mouse is the development of gene-driven ENU screens. This approach is based on parallel archives of genomic DNA and frozen sperm from G1 mutant males derived from ENU mutagenesis programmes. The DNA samples are screened for mutations in the gene of interest by PCR amplification of exon regions and the identification of base-pair substitutions by denaturing high-performance liquid chromatography (DHPLC). To detect a single event in a given gene at the chance of 90% requires the screen of approximately 2500 samples (Coghill *et al*., 2002). Upon identification of a DNA sample carrying a mutation, the corresponding mouse mutant can be recovered from the frozen sperm of the affected male by IVF. The proof of principle for this approach has recently been achieved by screening for mutations in the connexin 26 gene (Coghill *et al*., 2002).

In a related approach, ES cells are treated in vitro with ENU or other chemical mutagens (Chen *et al*., 2000; Munroe *et al*., 2000). ENU is able to induce loss-of-function mutations in the *Hprt* locus at a frequency of 10^{-3}, without affecting the germ-line competence of treated ES cells. For phenotype-driven screens, chimeric mice can be produced from bulk cultures of mutagenized ES cells followed by the backcrossing or intercrossing of ES cell–derived offspring. Alternatively, the gene-driven approach enables to isolate mutations in nonselectable genes of interest at the cellular level by screening DNA or cDNA samples derived from libraries of mutagenized ES cell clones. Using a library of 2060 mutagenized ES cell clones, Vivian *et al*. (2002) could detect 29 allelic mutations of the *Smad2* and *Smad4* genes by DHPLC-based heteroduplex analysis of RT-PCR products covering the entire coding regions of both genes.

5. Future developments

Over the last decade, a rich variety of mouse mutagenesis technologies has emerged. Appreciation of the power of mouse genetics to inform about human physiology and disease, and the ease of producing mutant alleles, has led to large-scale gene-trap and ENU mutagenesis programs. These efforts, together with the individual production of targeted mutants, have started to build a functional map of the mammalian genome. Despite these efforts, the absolute number of mouse mutants to date remains only a 10% fraction of the ~30 000 genes in the mouse genome. To improve this situation, several initiatives toward a genome-wide project for the systematic mutational and functional analysis of all mouse genes have recently emerged. The European conditional mouse mutagenesis programme (EUCOMM; Auwerx *et al*., 2004) puts priority on the development of conditional gene trap and generic conditional gene-targeting strategies. The US-based Knockout Mouse Project (KOMP; Austin *et al*., 2004) also proposes to saturate the genome by a combination of gene trapping and gene targeting, with less emphasis on conditional mutagenesis. It can be expected that these initiatives will lay the ground to build a more complete functional map of the mammalian genome over the next decade and promise a bright future for mouse genetics.

Specialist Review

Systematic mutagenesis of nonmammalian model species

Marcel van den Heuvel and David Sattelle
University of Oxford, Oxford, UK

1. Genes, mutants, and large-scale screens

Genetics (*see* Article 37, **Functional analysis of genes**, Volume 3 and Article 41, **Mouse mutagenesis and gene function**, Volume 3) used to be driven by an urge to understand the structure of the genome. How parts of the genome, and hence genetic traits, were linked on a chromosome provided important clues, resulting in an improved description of the morphology of the genome. However, following the discovery of the building blocks of DNA and the inevitable urge to fully decode the "book of life", genetics shifted its emphasis toward addressing the roles of individual genes. Genes had been shown to encode single proteins, each of which conferred a quite distinct function (e.g., an enzyme catalyzing a particular step in a metabolic pathway). Drawing on these basic findings, a new approach was developed to search for genes, which are required for a particular biological process. This necessitates a new concept of associated genes, based not on their location, but on their function instead. Hence, if we now wish to find all the genes involved in a particular process, our search for sets of functionally linked genes should cover the entire genome. To saturate the whole genome with mutants first requires mutagenizing, and then screening large numbers of animals. The extensive use of this approach has brought to center stage in biology two invertebrate animal species, the fruit fly, *Drosophila melanogaster* and the nematode worm, *Caenorhabditis elegans*. Their widespread use has less to do with their animal specifics and more with the ease and history of their use in the laboratory. The most important factor has been the ability to raise, study, and genetically characterize very large numbers of animals, each unique in its genetic composition. Using these animal "models", functional genetics in metazoan animals was initiated, leading to many large-scale functional mutagenesis screens over the last 30 years.

2. The fly and the worm: genetic model organisms used widely in mutagenesis studies

Each animal model has its genetic advantages as well as its limitations. For instance, Drosophila genetic screens for mutations affecting particular processes

are helped by the existence of so-called balancer chromosomes. These are the results of extensive genetic-building work to create functional chromosomes, which are however “completely” scrambled. Such chromosomes are useful to suppress recombination between homologous chromosomes and are therefore used in flies to stabilize chromosomes. In practice, this means that it is possible to keep a recessive mutation present in a genetic background (a specific chromosome) in a heterozygous, balanced state (the balancers also usually contain a lethal recessive mutation) over many (indefinite) generations. In addition, most of the balancer chromosomes also contain a dominant and several recessive markers, allowing the researcher to easily follow segregation of chromosomes, thereby removing the need for extensive testing to verify genetic background in a particular experiment. Drosophila, however, also suffers from some disadvantages; it has been difficult to generate a gene targeting approach (Rong *et al*., 2002). If one finds and wants to knock out a particular gene, the approach, therefore, still usually follows a random screen and genetic mapping. In addition, Drosophila represents an evolutionary highly developed insect, and thus might not be a good overall model for animal biology (Tautz, 2004). Animals that have been placed at evolutionary branchpoints may be more helpful in this aspect.

C. elegans, like Drosophila, has its limitations; it is an effective genome model for other rhabditid nematodes but sometimes comparisons with its more distant cousins among the nematodes can present problems, making further distant comparisons sometimes impossible. For example, there are a number of nematode genes that are absent from *C. elegans* and it appears that gene loss has played a key role in *C. elegans* genome evolution (Parkinson *et al*., 2004). Nevertheless, this 1-mm long, “simple” free-living nematode worm has an extremely rapid generation time (3 days at room temperature). The short life cycle, together with its hermaphroditic lifestyle, facilitate the maintenance and study of genetic strains. The consistency of development, the transparency of the worm, together with the relatively small number of cells, have made the first complete description of the cell lineage for an entire organism possible (Sulston *et al*., 1983; Sulston and Horvitz, 1977). The hermaphrodite has 558 cells at the first larval stage, rising to 959 in the adult. The adult nervous system has 302 neurons, and the “‘wiring diagram” of its 5000 synapses has been determined in exquisite detail (White *et al*., 1986). In *C. elegans*, the genetic map is anchored to (1) a physical map of the six chromosomes based on a combination of cosmid and yeast artificial chromosome (YAC) clones and (2) the entire genome sequence. Ready access to this outstanding resource has facilitated the analysis of gene function.

3. History

Gregor Mendel by publishing his “Versuche über Pflanzen-Hybriden” in 1865 provided an experimental demonstration that traits can be followed through subsequent generations, introducing, via plant breeding, concepts fundamental to what we now know as genetics. Thomas Hunt-Morgan and his followers took up this concept and for the first time used Drosophila to understand animal genetics. He can be regarded as the father of fly genetics. Sadly, one of the few remaining

descendants of his school of research, Ed Lewis, has recently died. He was awarded the Nobel Prize in 1995 for his work on the genetics of the *bithorax* complex of Drosophila genes and shared it with two other fly scientists, Christiane Nüsslein-Volhard and Eric Wieschaus. The mutants uncovered in the *bithorax* region were also perhaps the most extravagant example of a gene (or gene complex) leading to a clear trait: turning the fly's balance organs into wings (Lewis, 1978). The results had the superficial appearance of transporting Drosophila back in time, "creating" an evolutionarily ancient four-winged insect. This finding exemplifies the link between genes and evolution. Lewis experimented extensively with mutagenesis and showed that X-ray radiation cause chromosome deletions in Drosophila at any level. This work alerted the US government that radiation has no lower limit of effect (Scott and Lawrence, 2004). The two scientists with whom Ed Lewis shared his price set out to do an experiment that proved to be the jewel in the crown for Drosophila – to find all the genes involved in making a fly.

By the early 1960s, the central dogma of molecular biology (DNA makes RNA makes protein) was established and Sydney Brenner, who contributed so much to that core of knowledge, decided that a new experimental organism was required for a genetic approach to the organizing principles of the nervous system and embryonic development. He chose the nematode *C. elegans.* Among his criteria for selecting the worm were that it should be the simplest organism with traits of interest. Another was ease of manipulation. The first worm mutagenesis experiment was carried out in 1967, and in 1974 the results of the first characterization of ~100 genes were published (Brenner, 1974). This landmark publication was the basis for many subsequent mutagenesis experiments and screens. John Sulston and Bob Horvitz went on to determine the entire cell lineage of the worm (Sulston *et al*., 1983; Sulston and Horvitz, 1977) and in 1998 John Sulston, Alan Coulson, and colleagues at the Wellcome Institute Sanger Centre, UK, together with Bob Waterston and colleagues in the United States published the first draft sequence of the entire *C. elegans* genome, the first genome of a multicellular organism to be sequenced. Brenner, Sulston, and Horvitz shared the 2002 Nobel Prize in Physiology or Medicine for their discoveries.

4. Mutants: how to make a fly

Christiane Nüsslein-Volhardt and Eric Wieschaus took the idea of functional groupings of genes to a higher level by assuming that a set number of genes would be required to guide and steer the formation and development of the fly embryo. Perhaps stimulated by the findings of Ed Lewis on the *bithorax* complex, they saturated the whole fly genome with mutants, chromosome by chromosome, extracting and stabilizing any mutant that led to a recessive embryonic lethal endpoint. How this can be done is shown in Figure 1(a). They screened through the 1st (X), 2nd, 3rd, and 4th chromosomes in this way, screening in total probably around 40 000 lines, and isolated approximately 150 genetic complementation groups, each identifying several alleles in at least one gene involved in some aspect of embryonic development (Jürgens *et al*., 1984; Nüsslein-Volhard *et al*., 1984; Wieschaus *et al*., 1984). During the course of this work, they published

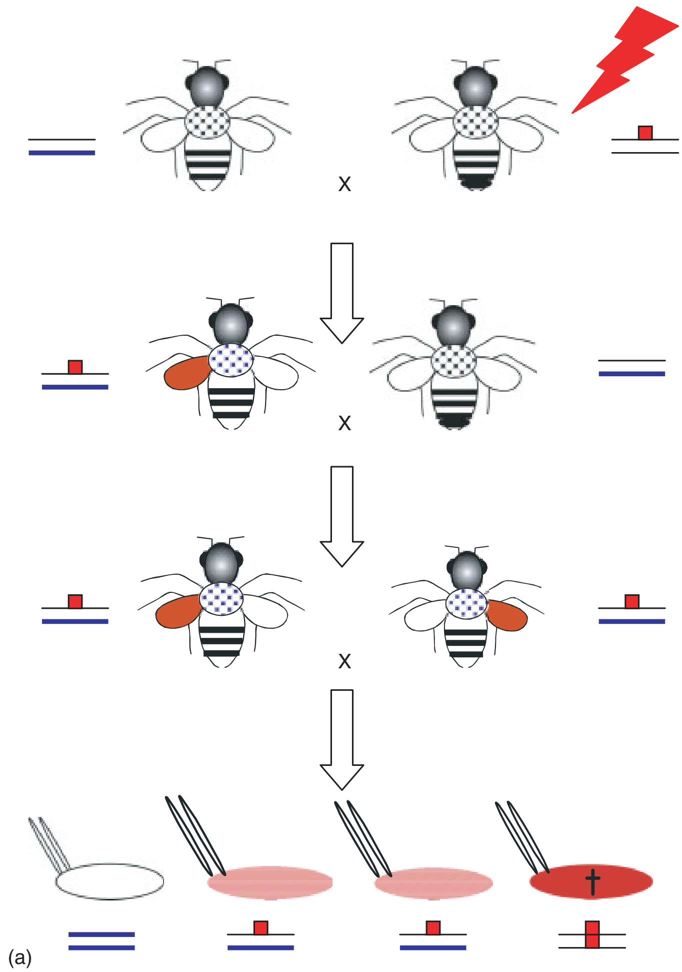

Figure 1 (a) Schematic outline of a simple F2 mutagenesis screen in Drosophila used to search for embryonic lethal recessive mutations. The male fly on the right is mutagenized (in red). The amount of mutagen is adjusted such that on average one hit per genome is reached. This is indicated as a single red box on one of this animal's chromosomes (both copies of a single chromosome are drawn). The male is crossed to a female with a balancer chromosome in her genetic make up, en masse (indicated as a blue line, with a "normal" chromosome as pair, black line). The mutagenized male chromosomes are thus balanced in the next generation (shown as a pair of a red box chromosome and a blue chromosome). The siblings for each of putative mutant chromosomes are intermated to create a stock (heterozygous for the original genetic defect), as well as generating offspring that can be studied. This is done initially as single pair crosses to stabilize the mutant background; the number of such (successful) crosses represents the final number of chromosomes screened. One-quarter of the offspring will be homozygous mutant (in red, shown as a pair of red boxed chromosomes) and should show the recessive phenotype (and if the phenotype is recessive lethal, die). (b) Schematic outline of a simple F2 screen in the nematode worm *Caenorhabditis elegans*. Wild-type worms are treated with the mutagen ethyl methanesulfonate (EMS). One-quarter of the F2 progeny will be homozygous for the mutated gene. Candidate mutant animals are isolated and cloned. The short life cycle of the worm, means that within very few days its F3 progeny can be examined to determine whether the candidate mutant breeds true

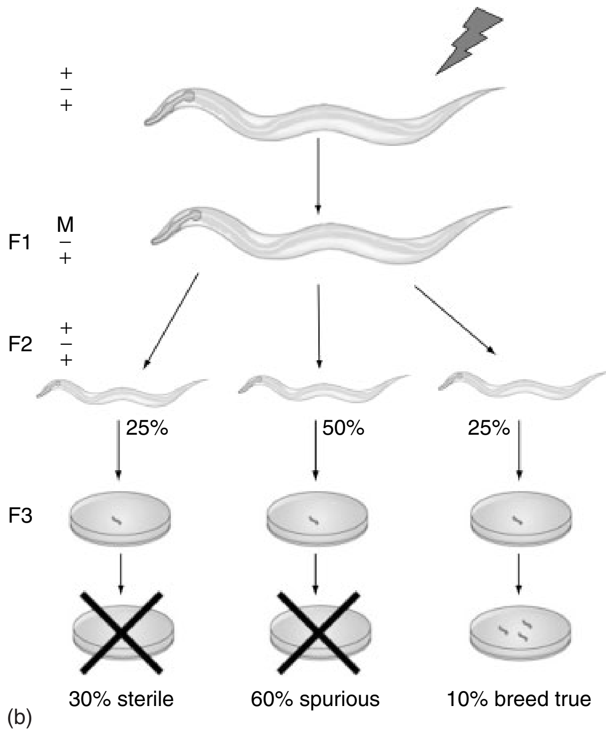

Figure 1 (*continued*)

a paper describing some remarkable findings (Nüsslein-Volhard and Wieschaus, 1980): segmentation in the fly appeared to be dependent on a simple building block pattern of gene activity. A first set of genes is required to assemble in large blocks, consecutive segments, covering the whole of the embryo. These large blocks in the thorax and abdomen of the future larvae are then again subdivided by another large group of genes that determine every other segment. Finally, there is a set of genes that seems to be required for each segment, mutants of which show segmentally repeated defects (Figure 2). Now, we may be used to the idea of the simplicity with which development takes its course, but it was an exciting and very surprising finding at that time.

However, this was not all that made these mutagenesis screens so important for the rest of the genetics and development community. With the advent of molecular biology, Drosophila played a defining role in the cloning of genes from its genome. In fact, possibly the first example of the route now almost standard of isolating a mutant, mapping the genome location and finding and cloning the gene, was not one of the mutants isolated in the large screens initiated by Jürgens, Wieschaus, and Nüsslein-Volhard but instead was a mutant isolated by Ed Lewis, *antennapedia* (*ant*) (Scott *et al.*, 1983). The cloning of the *ant* gene was also a primary example of clear evolutionary homology, a small protein domain in the encoded Antennapedia protein appeared to be homologous to a known bacterial DNA binding domain, now known as the homeo domain (Laughon and Scott,

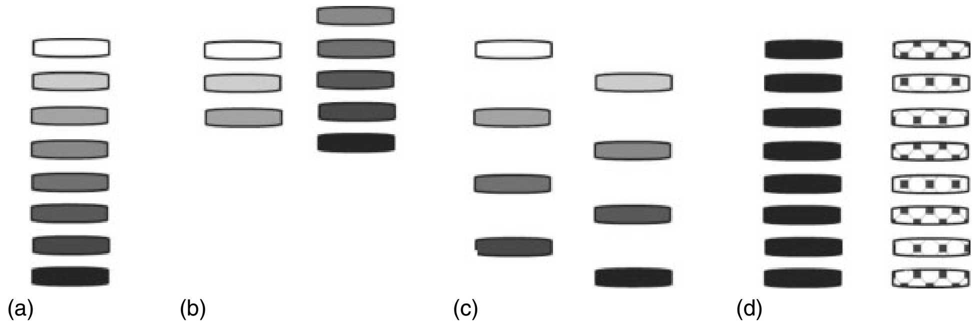

Figure 2 Schematic representation of mutant phenotypes of late embryos (cuticles) as described by Nüsslein-Volhard and Wieschaus (1980). (a) Normal cuticle pattern of abdominal segments, showing belts of denticles as boxes. Each belt in anterior to posterior direction has a unique character. (b) Phenotypes as observed in two hypothetical gap mutants, showing deletions of consecutive segments. (c) Phenotypes as observed in hypothetical pair rule mutants, showing deletions of every other segment. (d) Phenotypes as observed in hypothetical segment polarity mutants, each segment is altered in a similar manner (although the denticle belts still show differences in anterior to posterior direction across the animal)

1984). This was one of the first examples where a gene shown to function as a direct driver of a developmental process was evolutionarily conserved. It was certainly not the last.

Many of the genes isolated as mutants in the mutagenesis screens performed by Nüsslein-Volhard and Wieschaus have over the last decades proven to represent a set of evolutionarily ancient genes that are required to set up embryonic development in all animal phyla (and sometimes even in other phyla too). The fly thus has proven to be a very rich source of developmental genes, and almost all have been found through mutagenesis screens as described above. However, this is not the only contribution the fly has made to understanding developmental genes. Once a gene has been isolated and a mutant generated, this opens the door to functional analysis. Normally, such a mutant will have been isolated as part of a group of mutants leading to similar phenotypes (see Figure 2), and thus the gene can often be placed within a functional system. Further epistasis analysis, generating genetic combinations, then places the gene within the genetic (and often clear molecular) hierarchy in each group. The efforts to understand the genetic hierarchy leading to a patterned fly embryo, based on mutant screens has led to the isolation and functional characterization of large sets of genes and their encoded proteins, often enabling clear predictions regarding biochemical interactions. The processes driven by such gene hierarchies might not always be directly comparable from Drosophila to higher animals, such as human, and indeed evolutionarily they should not be but much can be learned from the analysis in flies (see (Tautz, 2004). Mutagenesis screens as described here had no prior genetic set up except to create a defined “normal” background amenable to mutagenesis and screening. They have been very useful in defining many processes and usually also resulted in a range of alleles for each gene. Refinement of the genetic background can however further assist in the recovery of more specific mutants and genes.

5. Mutants: what do you see?

The animal eye lends itself well to mutagenesis screens since, in most cases, visual abilities are not required in a laboratory environment. However comparing mutants and genes isolated from screens for mutants specifically affecting the fly eye, with genes now known to be required for eye development, has shown clearly that a large set of genes is required for eye development, and many of these are not represented by mutants with eye defects. Some of these genes are thought to be required at earlier steps in embryonic development (Cagan and Ready, 1989) and mutations would lead to severe developmental defects, that is, no fly, no eye. Thus, although the eye seems a perfect organ to screen for genes that could have a potential role in, for instance, human eye anomalies, it has not been easy to find these. However, an elegant deployment of the late differentiating Drosophila eye has provided a very useful model.

The tissue from which the eye of the fly develops remains a naïve field of cells until late in the larval stage when a front of differentiation sweeps through the eye field to generate the stereotype insect compound eye pattern (Tomlinson, 1985). It is thought therefore that the generation of the different cells within each unique entity of the compound eye is dependent on local cell interactions (Ready *et al*., 1976). Through traditional behavioral screens, a mutant in one of the neuronal, light-sensitive cells (in this case UV sensitive) had been isolated, called *sevenless* (*sev*) (the 7th omatidial cell, out of a total of eight cells, disappears, hence the name) (Harris *et al*., 1976). The gene was cloned, sequenced, and its expression localized (Hafen *et al*., 1987; Tomlinson *et al*., 1987). It appeared that the *sev* gene encoded a tyrosine kinase receptor. Such proteins were known as important in oncogenesis in humans and had been studied in cell culture. The appearance of an onco-protein in a developmental decisions process was seen as a prime example of a signaling pathway determining a cell's fate. Key questions remaining were: how does it function, what is its ligand and how does it signal to induce the R7 fate? Extensive screens for other genes leading to mutant phenotypes only affecting the R7 cell did not result in new mutants. To try and find these, a screen was designed using what we now know as a sensitized genetic background. Instead of looking for mutants in as clean and normal a genetic background as possible, the principle of these screens is to create a background already on the brink of failure within a very specific process. Subsequently, introducing mutations into such a background, for example by only reducing the activity of a gene by half (heterozygous), could tip the balance over and lead to a phenotype. Such screens are therefore based on dominant suppression or enhancement of a subtle phenotype. The mutagenesis screen as set up and performed by Simon *et al*. (1991) introduced a very useful concept into screening for specific biological processes in the fly and one that has been repeated many times (Haines and van den Heuvel, 2000). The screen in the fly eye using *sev* as well as modified allelic varieties of *sev*, resulted in the isolation of mutants encoding downstream components (Simon *et al*., 1991). Some of these genes had already been isolated as putative oncogenes in higher animals, such as Ras (for review see Varmus, 1984), again indicating that flies possess mechanisms for driving differentiation and proliferation, very similar to those of higher animals. In addition, further mutagenesis work led to the addition of new functional assays

designed to understand Ras function, through for instance the isolation of novel mutants in this signalling pathway and new functional interactions characterized (Gaul *et al*., 1992; Hariharan *et al*., 1991; Simon *et al*., 1991; Wolff and Ready, 1991), as well as leading to the isolation of downstream effectors (Brunner *et al*., 1994a; Brunner *et al*., 1994b; Chang *et al*., 1995; Lai and Rubin, 1992). The isolation of these mutants and characterization of the homozygous phenotype did confirm the prediction: most are homozygous embryonic lethal.

6. Mutants: discovering where drugs act

Most mutants of *C. elegans* have been generated using the chemical mutagen, EMS (ethyl methane sulphonate) to generate mutations in sperm and oocytes. Many of the mutations generated in Brenner's original screen were visible recessive mutations, identified in a simple F2 screen (Brenner, 1974) (Figure 1b). Worms with mutant phenotypes are then transferred to new plates to test whether the phenotype is transmissible to the next generation. In a typical screen 12 000 copies of any particular gene are assayed. The frequency of recovery of mutations is about one in 2000 copies of the gene. Using this approach, Brenner identified 619 mutants with visible phenotypes. An excellent account of *C. elegans* genetic screens is given by (Jorgensen and Mango, 2002).

An example of the utility of a chemistry-to-gene screen is that initiated by Brenner using levamisole, an antiparasitic drug (Brenner, 1974). Levamisole is a broad-spectrum antiparasitic drug widely used to eradicate roundworm infestations in livestock and humans (World Health Organization **http://www.who.int/topics/en/**). *C. elegans* resistant to 100-μM levamisole were characterized by their ability to migrate across an agar plate containing the drug, more quickly than sensitive wild type worms and it was noted that some had characteristic phenotypes such as uncoordinated movement or twitching. Brenner surmised that levamisole acts as an acetylcholine (ACh) agonist since its effect resembles the paralysis produced by the acetylcholinesterase (AChE) inhibitor, lannate. Later pharmacological studies on cut worms by Lewis *et al*. (1980) showed that levamisole-resistant mutants lack functional muscle nicotinic acetylcholine receptors (nAChRs) and the loss of high-affinity levamisole binding in two mutants (*unc-50* and *unc-74*) led to the notion that the affected genes encode for proteins involved in levamisole receptor processing and assembly (Lewis *et al*., 1987).

Now, nearly all of the 12 genes that mediate levamisole resistance have been identified. Five encode the nAChR subunits, UNC-29, LEV-1, UNC-38, UNC-63, and LEV-8 (Fleming, 1997; Culetto *et al*., 2004; Towers *et al*., 2005). *C. elegans* possesses one of the most extensive and diverse nAChR gene families known, consisting of at least 27 subunits that have been divided into subgroups based on sequence homology (Jones and Sattelle, 2004). As expected from the hypercontraction induced by levamisole, all the five nAChR subunits identified from this chemistry-to-gene screen are expressed in body wall muscle. Recent functional studies show that these subunits are important components of levamisole-sensitive nAChRs (Richmond and Jorgensen, 1999; Culetto *et al*., 2004; Towers *et al*., 2005).

The other levamisole-resistance genes appear to encode molecular components associated with nAChR assembly and function. These include UNC-50, a novel transmembrane protein, the mammalian homolog of which, UNCL, is an inner nuclear membrane RNA binding protein that increases cell-surface expression of vertebrate nAChRs ($\alpha 4/\beta 2$) when coexpressed with them in *Xenopus laevis* oocytes and COS cells (Fitzgerald *et al*., 2000). The *lev-10* gene has shown to encode a transmembrane protein required for postsynaptic aggregation of nAChRs at the neuromuscular junction (Gally *et al*., 2004). LEV-10 interacts extracellularly with either nAChR subunits, or nAChR-associated proteins. Other levamisole resistance genes regulate signal transduction downstream of nAChR activation. UNC-68 is the ryanodine receptor, which is expressed in body-wall muscles and is necessary for normal locomotion. It plays a role in intracellular Ca^{2+} regulation and is also a validated pesticide target site (Maryon *et al*., 1996). The *unc-22* and *lev-11* genes, respectively encode twitchin, which contains fibronectin typeIII, immunoglobulin, and protein kinase domains (Benian *et al*., 1993) and tropomyosin, which regulates muscle contraction (Kagawa *et al*., 1997).

Thus, a chemistry-to-gene screen using levamisole not only identifies a subset of nAChRs from a very large family that are targeted by an antiparasitic drug, but also provides insights into cellular pathways linked with nAChR function. Among the gene products acting upstream and downstream of the drug target is another validated pesticide target. Thus, a chemical based screen thereby demonstrating that this approach not only uncovers the target of a known chemical but can also be used to identify new drug targets. Furthermore, as demonstrated by studies on UNCL, such screens have the potential to shed light on the function of human genes.

Other screens in use in *C. elegans* include modifier (enhancer suppressor screens) screens that search for second site mutations that either exacerbate or ameliorate the phenotype of the first mutation (such as described above for Drosophila). Multigenerational, microscopy-based and laser ablation screens have been pursued successfully in the worm as well as screens for lethal mutants (see Jorgensen and Mango, 2002).

7. Genetics in forward and reverse gears

The worm has about 20 000 genes fewer than 10% of which have been identified by mutation. Of these, 575 have been cloned and characterized at the molecular level. About 70% have a mammalian counterpart and about 50% of human disease genes have a *C. elegans* equivalent (Culetto and Sattelle, 2000), hence the interest in further understanding the remaining genes. Genes that are specific to nematodes are also of interest both from an evolutionary perspective and from a practical viewpoint in designing new, safer antiparasitic drugs (2.9 billion people have parasitic nematode infections, there are substantial losses in livestock and crop damage worldwide is estimated at $80 billion). Genetics can move forwards through the mapping of a novel phenotype to discover the gene(s) involved and then addressing function. A genome-wide mutagenesis program is under way in *C. elegans* with the aim of generating a deletion mutant for every gene.

Now that we have the complete genome sequence for fly (Myers *et al*., 2000), worm and other organisms too, we can also deploy to powerful effect a genetic reverse gear (*see* Article 44, **The *C. elegans* genome**, Volume 3 and Article 45, **The *Drosophila* genome(s)**, Volume 3). An example of the new reverse genetics can be illustrated in the genomewide RNA interference (RNAi) screens carried out by, for example, the Ahringer (Kamath *et al*., 2003) and Plasterk (Simmer *et al*., 2003) laboratories. This work was based on the original breakthrough by Fire *et al*. (1998) who showed that introducing double-stranded RNA (dsRNA) for a particular gene into worms resulted in the knockdown of the function of that particular gene. Such high-throughput screens in *C. elegans* are facilitated by the finding that the dsRNA can be delivered to worms via the noninfective *E. coli* strain of bacteria on which they feed. The results from the large-scale screens covering 86% of the genome showed that 1722 (10.3%) showed phenotypes. Rerunning the screens with particular mutants hypersensitive to RNAi is now providing access to new genes (Simmer *et al*., 2003).

8. Genomes and mutagenesis

The completion of the Drosophila genome sequence has led to some new as well some modified mutagenesis protocols and of course has sped up the cloning of genes underlying already mapped mutants. The increasing evidence that many genes are required throughout the development and life of an animal at various places and at different times indicated that often gene knock out would not lead to a full spectrum of this gene's function. To bypass the early functions of genes, experimental strategies described above can be used but another way of bypassing earlier gene requirements is to make cells homozygous mutant for such a gene only at certain times and/or in selected places. Somatic homozygous clones can be induced by recombination for instance as a results of chromosome insult. However to regulate this, increase efficiency and localization, yeast recombination sites (and the required enzymatic activity) were introduced at fixed places through out the fly genome, the so-called FLP-FRT system (Chou, 1992; Ryder *et al*., 2004; Xu and Rubin, 1993) (Figure 3a). The end result of these experiments is a pool of heterozygous cells within which homozygous mutant (and homozygous marker expressing cells) clones are found. This technique is very well placed for analyzing the effects of signalling pathways in fields of cells.

However, recombination as induced by this system can also be used to drive the generation of chromosomal deletion stocks. By generating large numbers of individual insertions of the recombination enzyme (FLP) recognition site (FRT) across the genome, intrachomosomal recombination can be induced which leads to the loss of the chromosome area in between two FRT sites present in cis on the chromosome. Random FRT sites have now been mapped to their chromosomal location by sequence analysis and mapping onto the genome sequence. It is possible therefore to create a custom-built deletion across a defined chromosome area (see Parks *et al*., 2004 and **http://www.drosdel.org.uk/**) using this system.

The FLP-FRT lines are all based on the use of the P-element system to generate fly transgenics (Spradling and Rubin, 1982). Insertional mutagenesis has been used

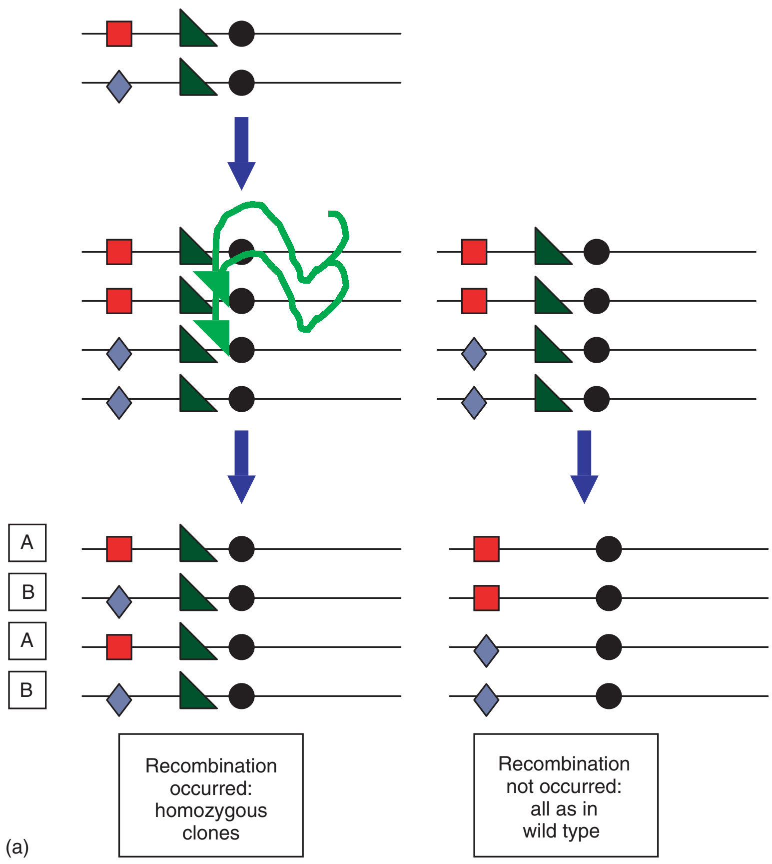

Figure 3 (a) Schematic outlining use of FRT-FLP system to generate clones. In a heterozygous mutant background (as represented by a pair of chromosomes, one carrying a mutation: red box, the other expressing a blue marker gene), where each of the arms on which your mutant allele is present, carry, close to the centromere (black circle), a recognition site for a yeast derived recombinase enzyme (Flippase, FLP); these sites are represented by a green triangle and also known as FRT sites. When the DNA is duplicated (cell undergoing division), a pulse of Flippase activity would lead to recognition of the FRT sites by Flippase (light green triangle with line) and induce recombination between the two chromosomes (shown on left). If the cells undergo division but no Flippase activity is present, only random recombination would take place (very rare). In either case, the chromosomes will be separated according to the normal pattern, where A and A are joined (and B and B). In the case where no recombination has taken place, this leads to two daughter cells with the same genetic build-up as the parent cell (shown on right). If recombination has taken place, the two daughter cells are different, one being homozygous for your mutation, the other homozygous for the marker. (b) Schematic outlining use of UAS-GAL4 system in flies. The Gal transcription factor protein recognizes very specifically, a binding site known as UAS (Upstream Activating Sequence). When this site is cloned in front of Your Favorite Gene (YFG), expression of GAL4 protein in a cell will turn on transcription of YFG and lead to production of product. To use this system efficiently, large numbers of GAL4 driver stocks have been generated, each expressing GAL4 in different places and at different times during the fly life cycle. These can be crossed to your animal transgenic for the UAS-YFG construct. In this way, general lethality by expression of YFG can be overcome since only progeny will be affected and the cross can be set up endlessly. In addition, highly specific cells can be targeted by using GAL4 lines expressed in such cells only. Further sophistication to the system has been added by using a GAL4 inhibitor, GAL80

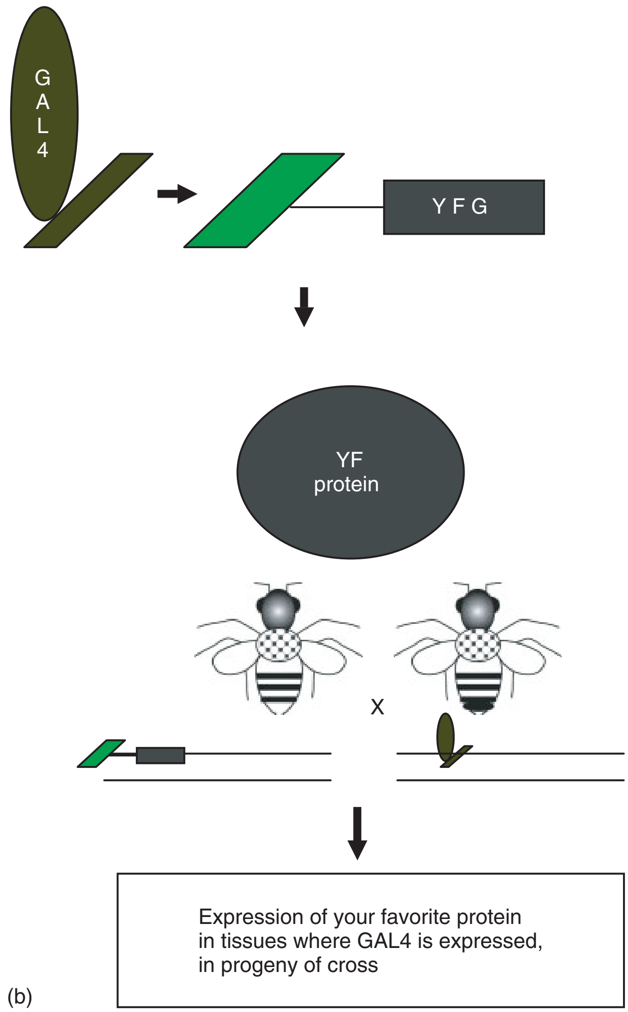

Figure 3 (*continued*)

extensively in Drosophila to target genes, generate gene expression tags as well as dominant enhancer traps (e.g., Kania *et al*., 1995; Kelso *et al*., 2004; Rio and Rubin, 1985; Rørth *et al*., 1998). Often such insertional elements are not fully random as to choice of insertion site, and new elements with either more random insertion preferences or just with altered choices have been developed (Bonin and Mann, 2004). All of such methods are however not specific to flies, although they are highly developed and often intricately linked to specific scientific questions. General methods of screening and analyzing gene function such as RNAi have also been applied in flies, mostly in cells (Kiger *et al*., 2003). However, new approaches by generating inducible constructs (UAS-GAL4 system, Brand and Perrimon, 1993) (Figure 3b) encoding hairpin loop mRNA stretches for a particular gene have been tested.

9. General conclusion and prospects

As the few examples given here illustrate, mutagenesis coupled with carefully designed screens of various kinds has proved extremely productive in ascertaining gene functions and in discovering the components of pathways involving the products of many genes. We have chosen examples of how such approaches have contributed to developmental biology and neurobiology but many other examples could have been selected. In the future, forward genetic screens will continue to be important especially when combined with expression profiling via DNA microarrays, the expanded use of gene reporters, RNAi, and the increasing use of interactome maps summarizing protein–protein interactions. The use of sensitized screens in both model organisms seems set to increase. A major challenge for the future will be addressing the functions of those genes (estimated as approximately two-thirds of the *C. elegans* genes) for which it is estimated that no visible, lethal, or sterile phenotype can be generated. As outlined in this chapter, the ability to look randomly for genetic aberrations that influence a biological process, without any preconceptions, is important and has led to a wealth of new discoveries.

Short Specialist Review

Functional genomics in *Saccharomyces cerevisiae*

Kara Dolinski and Olga Troyanskaya
Princeton University, Princeton, NJ, USA

1. Introduction

The availability of the complete *Saccharomyces cerevisiae* genome sequence, published in 1996 (Goffeau *et al*., 1996), stimulated much innovation in genome-scale experimental approaches, including the development and implementation of the many uses of DNA microarrays, the systematic deletion (Winzeler *et al*., 1999; Deutschbauer *et al*., 2002; Giaever *et al*., 2002; Steinmetz *et al*., 2002) and genetic footprinting studies (Smith *et al*., 1995; Smith *et al*., 1996), several genome-wide collections of gene and promoter fusions (e.g., Ross-Macdonald *et al*., 1997), as well as a number of genome-wide protein- and gene-interaction studies. The goals of these very different approaches are nonetheless the same: to determine the function of all the genes in the yeast genome. A number of bioinformatics approaches are beginning to be applied to predict gene function on the basis of these large-scale, heterogeneous data sets. Because genome-wide experimental methods often sacrifice specificity for scale, an integrated analysis of multiple types of experimental data is necessary to make accurate predictions of gene function on such a large scale. After discussing the functional genomics data currently available for *S. cerevisiae*, we describe how a probabilistic integration method can use these data to predict gene function.

2. Available functional genomics data in *S. cerevisiae*

The avalanche of functional genomics data began with the development of microarray technology in the mid-1990s (Schena *et al*., 1995; Shalon *et al*., 1996; Brown and Botstein, 1999). Gene expression microarrays generate mRNA expression profiles of genes on the scale of the entire genome. More recently, microarrays have now been applied to map protein–DNA interactions (e.g., Ren *et al*., 2000; Iyer *et al*., 2001; Lieb *et al*., 2001; Kurdistani *et al*., 2002; Kurdistani and Grunstein, 2003; Ng *et al*., 2003; Harbison *et al*., 2004) and to characterize protein interactions (Zhu *et al*., 2001; *see also* Article 97, **Seven years of yeast microarray analysis**, Volume 4). In addition to these various microarray experiments, high-throughput interaction studies have also been carried out, including large-scale

Table 1 Some sources of functional genomics data collections for *S. cerevisiae*

genetic interaction screens (Tong *et al*., 2001; Ooi *et al*., 2003; Tong *et al*., 2004), two hybrid analyses (Uetz *et al*., 2000; Ito *et al*., 2001; Hazbun *et al*., 2003), mass spectrometry (Gavin *et al*., 2002; Ho *et al*., 2002), and combined mass spectrometry/chromatography (aka MudPIT) (Washburn *et al*., 2001; Washburn *et al*., 2002). A wealth of large-scale phenotype data are available in *S. cerevisiae*, including results from the Saccharomyces Genome Deletion Project (Winzeler *et al*., 1999; Deutschbauer *et al*., 2002; Giaever *et al*., 2002; Steinmetz *et al*., 2002) and from large-scale insertional mutagenesis (Smith *et al*., 1995; Smith *et al*., 1996; Kumar *et al*., 2002). In addition, there are databases available that contain quantitative data from analysis of morphological mutants (SCMD, see Saito *et al*., 2004) and growth aberrations (PROPHECY, see Warringer *et al*., 2003).

Table 1 lists some of the major collections of yeast functional genomics data. All these sites allow public data download in addition to a web interface, facilitating bioinformatics analysis of the data. The yeast databases MIPS and SGD also distribute some of these large-scale data sets. MIPS (**ftp://ftpmips.gsf.de/yeast/**) and SGD (**ftp://ftp.yeastgenome.org/pub/yeast/**) both provide data for bulk download via ftp. In addition, SGD has developed a lightweight version of SGD called SGD Lite (**http://sgdlite.princeton.edu/**), which has some of the yeast data in a PostgreSQL database meant for simple, local installation.

3. Standards in the functional genomics community

Adherence to community standards for data format, annotation, and distribution is essential to enable full utilization of data generated by large-scale experiments through comparison and integration of multiple data sets. The Open Biological Ontologies (OBO) site is a web page that provides links to various ontologies and standards projects, including the Microarray Gene Expression Data (MGED)

Society (see **http://www.mged.org/**, Spellman *et al*., 2002; Causton and Game, 2003) and the Gene Ontology project (GO, **http://www.geneontology.org**, Ashburner *et al*., 2000; *see also* Article 82, **The Gene Ontology project**, Volume 8). Also available through the OBO site are links to the Proteomics Standards Initiative, which has created standards for protein–protein interactions as well as mass spectrometry data (Hermjakob *et al*., 2004a), and BioPAX, which has been developing a common exchange format for pathways data (see **http://www.biopax.org/**).

4. General probabilistic integration of functional genomics data

To address the need for a generalizable method for comprehensive data integration, an approach should combine heterogeneous data types of various levels of accuracy in an algorithmic fashion and should also easily adapt to new data sources. Recently, several such approaches have been introduced, including methods that focus on modeling one or several specific data types (Friedman *et al*., 2000; Pavlidis and Noble, 2001; Ihmels *et al*., 2002; Imoto *et al*., 2002; Segal *et al*., 2003) and more general integration approaches (Jansen *et al*., 2003; Troyanskaya *et al*., 2003; Lanckriet *et al*., 2004).

The advantage of general approaches to data integration is their adaptability. For example, MAGIC (Multisource Association of Genes by Integration of Clusters), a general probabilistic approach to data integration, uses a Bayesian network architecture that can easily incorporate new data sources, datasets, and analysis methods (Troyanskaya *et al*., 2003). It incorporates expert knowledge in the prior probability parameters in the Bayesian framework or learns from available data, thus formally integrating relative accuracies of different experimental and computational techniques in the analysis and minimizing potential bias toward well-studied areas in its reasoning. In addition, Bayesian networks are generally robust to noise in prior probabilities and in training data. These characteristics of Bayesian networks yield high accuracy of gene function predictions (the prototype MAGICsystem can achieve accuracy of up to 83% for the high-stringency predictions), and the probabilistic nature of the system provides confidence levels for each output.

The MAGIC integration system takes as input groupings (or clusters) of genes based on each experimental data set (e.g., shared transcription factor binding sites, protein–protein interaction, or coexpression data). The system represents all input groupings as gene i–gene j pairs with corresponding scores s_{ij}. The score s_{ij} corresponds to the strength of each method's belief in the existence of a relationship between gene i and gene j. The score $s_{ij} > 0$ if gene i and gene j appear in the same cluster or grouping or if they interact on the basis of an experimental method, and it can be binary (e.g., results of coimmunoprecipitation experiments), continuous or discrete (e.g., $-1 \leq s \leq 1$ for Pearson correlation). MAGIC's Bayesian network combines evidence from input groupings and generates a posterior belief for whether each gene i–gene j pair has a functional relationship. For each pair of

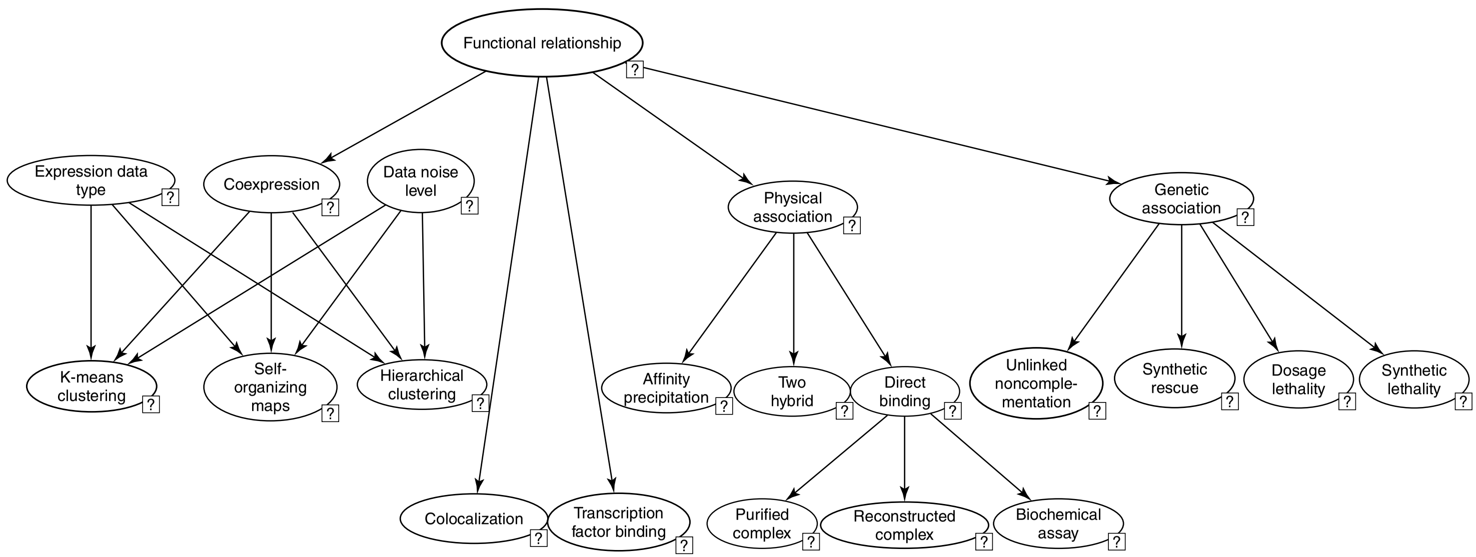

Figure 1 A structure for the Bayesian network in MAGIC. The network is instantiated with evidence (at the bottom nodes) for each pair of genes in the yeast genome, and the final confidence level is produced on the basis of the evidence for biological relationship available for each pair of genes and on the prior probabilities encoded in the network conditional probability tables. This figure is adapted from Troyanskaya *et al*. (2003)

genes, the network essentially asks the following question: "What is the probability, based on the evidence presented, that products of gene *i* and gene *j* interact or are involved in the same biological process?" MAGIC's Bayesian network structure (Figure 1) was determined through consultation with experts in yeast genomics and microarray analysis, and the prior probabilities can be either based on expert consultation or learnt from example data (such as functional annotations of genes with the Gene Ontology biological process annotations).

This success of function prediction based on heterogeneous data demonstrates the potential of sophisticated data integration algorithms. Further development of such computational methods combined with increased availability of large-scale functional genomics data in downloadable standardized formats should enable accurate prediction of function for most unknown yeast proteins. These predictions, followed by targeted laboratory experiments, may enable fast and relatively low cost annotation of the entire yeast genome.

Short Specialist Review

The *C. elegans* genome

Jonathan Hodgkin
University of Oxford, Oxford, UK

1. The *C. elegans* genome

The genome of the small nematode worm *Caenorhabditis elegans* contains just over 100 million base pairs. It is one of the smallest of all known animal genomes, and partly for this reason, it was the first fully sequenced genome for any multicellular organism, being essentially completed in 1998 (*C. elegans* Sequencing Consortium, 1998).

The nuclear genome of normal diploid *C. elegans* hermaphrodites is organized into five pairs of autosomes (size range 13–21 Mb) and one pair of X chromosomes (17 Mb). The alternative sexual form, the male, has only one X chromosome and there is no Y chromosome. The small mitochondrial genome (13.8 kb) has also been completely sequenced. Nematode chromosomes are unusual in that they are holocentric, with multiple kinetochores, and lack extended regions of centric heterochromatin. *Caenorhabditis elegans* also has relatively little repetitive sequence. As a result, it has been possible to achieve full sequence coverage, telomere to telomere, for all six chromosomes, resulting in a precise figure of 100 277 975 nucleotides for the entire nuclear genome.

Extensive annotation of the genome has revealed approximately 19 900 predicted protein-coding genes, as well as about 600 tRNA genes, 200 tRNA pseudogenes, 55 copies of the large ribosomal RNA genes, 110 copies of the 5S rRNA gene, and the usual eukaryotic sets of snRNAs, scRNAs, snoRNAs, and other functional RNA genes. Micro-RNA genes, which were first discovered in *C. elegans*, number at least 100. Repeat sequences account for about 6% of the genome; some of these form tandem arrays that may serve as kinetochores. Some of the other repeat sequences belong to known transposon families, most of which are currently inactive although mobilization can be achieved. Telomeres are conventional, with TTAGGC tandem repeats, but there are no specialized subtelomeric regions.

The total percentage of protein-coding DNA is high, for a multicellular organism (27%), and there appear to be relatively few pseudogenes and almost no processed pseudogenes. About one-quarter of all genes are organized into operons, in which between two and eight genes are cotranscribed from a common promoter as a polycistronic transcript (Blumenthal *et al*., 2002). This primary transcript is broken up into separate monocistronic mRNA molecules by trans-splicing: a small leader RNA, termed SL2, transcribed from separate loci, is spliced onto the 5′ end of

each cistronic sequence, in a process related to conventional cis-splicing. About 70% of all genes also undergo general trans-splicing to acquire SL1, a small leader RNA similar to SL2, at the 5′ end of the mRNA. Organization into operons seems to be a peculiarity of the *C. elegans* genome, rarely found in other invertebrate genomes, and possibly related to the compactness of the genome. Some operons contain genes of related function, but many do not.

Gene number is surprisingly high when compared to an estimate of about 14 000 genes for *Drosophila*, which is a substantially more complex animal in terms of anatomy, development, and behavior. Various factors may contribute to this large number of genes, such as a high level of duplication of genes and genomic regions, as compared to other eukaryotic genomes. Another contributory factor may be a relatively low level of alternative splicing – currently, only about 11% of *C. elegans* genes are known to generate more than one mRNA isoform, which is lower than the estimates for other animal species. Protein diversity may therefore be generated more by expanded gene families than by alternative splicing.

Some gene families appear to have undergone considerable expansion during the evolution of *C. elegans*. Notably, there are over 200 genes encoding DNA-binding proteins of the nuclear hormone receptor class, and about 1000 genes encoding seven-pass transmembrane proteins, which are probably G-protein coupled receptors (GPCRs). The large number of these predicted GPCRs may be related to the sophisticated chemosensory repertoire of *C. elegans*. Detection of odorants provides the worm with most of its sensory information about the environment.

Multiple postgenomic approaches are being used to verify and investigate all the genes predicted to exist in the *C. elegans* genome. Many of the predicted genes have no obvious homologs in other organisms, and their function is usually unknown. Large sets of ESTs (expressed sequence tags) have been generated, along with SAGE (serial analysis of gene expression) analyses, in order to define the transcriptome. Transcripts for predicted genes have been systematically searched for, by Reverse Transcription Polymerase Chain Reaction (RT PCR). Systematic expression studies have been undertaken by in situ hybridization, by microarray analysis, and by the generation of transgenic lines carrying reporter genes fused to Green Fluorescent Protein (GFP) or lacZ markers. Protein interaction maps have been constructed using high-throughput yeast 2-hybrid screens (Li *et al*., 2004).

In terms of function, large numbers of genes have been investigated by conventional forward mutagenesis, using chemical and transposon mutagenesis. Reverse genetic programs for systematically generating deletions in targeted genes have been established. Large-scale functional studies have been carried out by means of RNAi (RNA interference), which provides an effective means of suppressing expression of most, though not all, *C. elegans* genes. RNAi can be elicited most easily by feeding worms on bacteria expressing double-stranded RNA for a targeted gene, and “feeding libraries” have been generated that allow RNAi to be applied to most of the worm’s genes (Kamath *et al*., 2002). The resulting data allow preliminary assignment of function to about 23% of genes. RNAi tests on the remaining 77% reveal no obvious function, however, for a variety of possible reasons, such as subtle or redundant activities, or incomplete knockdown by RNAi.

The RNAi data, together with other information, provide evidence for long-range order in the *C. elegans* genome, with some clustering of genes affecting related

biological processes. There are also conspicuous differences between the autosomes and the X chromosome, with a reduced frequency of essential genes being found in the X chromosome. The five autosomes all show a similar arrangement of a distinct central region, or cluster, flanked by arms of roughly equal size. The cluster regions are somewhat more gene-dense and show reduced recombination levels; the genes in the clusters show higher levels of conservation and are more frequently essential, as compared to the genomic average. In contrast, the arm regions have higher levels of recombination, contain more gene families and more genes that lack obvious homologs in other organism. The origin and significance of these large-scale features are unknown.

Investigation of the *C. elegans* genome has been greatly aided by extensive sequencing of closely related nematode species. In particular, the genome of *Caenorhabditis briggsae* has been shotgun sequenced at 10x coverage, allowing assembly of most of its genome (Stein *et al*., 2003). The two species diverged possibly 100 million years ago, and the two genomes have experienced multiple rearrangements, mostly intrachromosomal. Comparison of the *C. elegans* and *C. briggsae* genomes has permitted confirmation of many predicted genes and identification of conserved noncoding regions such as regulatory sites. The model organism database WormBase (**http://www.wormbase.org/**) provides an integrated and continually updated overview of the genomes of *C. elegans* and related species.

The *Drosophila* genome(s)

Steven Russell and Casey M. Bergman
University of Cambridge, Cambridge, UK

The first release of the 118-Mb *Drosophila melanogaster* euchromatic genome sequence, generated by a combination of map-based and whole-genome shotgun strategies (Adams *et al*., 2000), has been updated several times, improving sequence and annotation quality (Celniker and Rubin, 2003). With the essential use of EST and cDNA sequences, release 4.0 predicts 13 472 genes producing 18 746 protein-coding transcripts. Less-stringent annotations suggest additional genes, at least some of which are supported by microarray and RNAi studies (Boutros *et al*., 2004). Along with the protein-coding complement of the genome, there have been improvements in annotating transposable element sequences (Kaminker *et al*., 2002), an effort to assemble the 60 Mb of heterochromatin (Hoskins *et al*., 2002) and computational attempts to identify microRNAs (Brennecke and Cohen, 2003). This ongoing work aims at generating a high-quality contiguous genome sequence and functional annotation encompassing the entire euchromatic genome with as much of the heterochromatin as possible. All sequence gaps in the euchromatin are scheduled to be closed by the beginning of 2005; currently, there are 23 gaps in release 4. Annotation is, of course, an ongoing effort. Physical gaps and large tandem repeat regions are also being completed as a part of finishing the heterochromatic sequence. As it stands, in terms of scaffold integrity and annotation accuracy, the *D. melanogaster* euchromatin represents a gold standard for genome sequences.

The success of the whole-genome shotgun strategy in *D. melanogaster* suggested that other *Drosophila* species could be rapidly sequenced as resources for comparative genome analysis. The first, *D. pseudoobscura*, was chosen on the basis of estimates that unconstrained DNA sequence divergence should be "saturated" between *D. pseudoobscura* and *D. melanogaster* (Bergman *et al*., 2002); thus, sequences conservation between these species should imply functional constraint. The first draft of the *D. pseudoobscura* sequence and whole genome comparisons with *D. melanogaster* are now available (**http://pipeline.lbl.gov/cgi-bin/gateway2?bg=dm1**). Two further efforts to sequence an additional 10 *Drosophila* species are underway; the first, focusing on developing resources for population genetic and evolutionary analysis of two species closely related to *D. melanogaster* – *D. simulans* and *D. yakuba*; the second, to sequence a panel of eight species spanning a range of divergence distances in the genus. As of August 2004, over two million sequencing reads and preliminary WGS assemblies exist

for five of these species (**http://rana.lbl.gov/drosophila/multipleflies.html**). The depth and richness of genome sequences now available in *Drosophila* will provide invaluable resources for the comparative analyses of genes and cis-regulatory sequences (Bergman *et al*., 2002; Grad *et al*., 2004).

Complementing the sequence(s), several genomics resources are available; these include 2-hybrid libraries (Giot *et al*., 2003), RNAi collections (Boutros *et al*., 2004), and oligonucleotide and amplicon microarrays (Johnston *et al*., 2004). Such resources increase the utility of the fly as a system for integrative biology, for exploring conserved aspects of development, and as a model for human diseases. The strength of *Drosophila* has always been its sophisticated array of genetic tools and the genome sequence has strengthened this. Transposon insertions are now easily mapped with base-pair precision to the genome sequence, and the Gene Disruption Project, which aims at generating insertions in every gene, has currently tagged over 40% of *Drosophila* genes (Bellen *et al*., 2004). In addition, collections of transposons carrying sites for the yeast site-specific FLP recombinase are being used to make precisely defined chromosomal aberrations such as second-generation deficiency kits (Ryder *et al*., 2004; Parks *et al*., 2004). Complementing classical approaches, forward genetic strategies utilizing transposons for GAL4-inducible gene expression and protein trapping are identifying genes involved in a variety of processes. Finally, the ongoing development of high-density SNP maps permits rapid association of mutant phenotypes with individual genes. Thus, the genome sequence has accelerated the large-scale genetic analysis of the fly by facilitating phenotype-to-genotype association.

As a model for human disease, the fly genome is excellent for uncovering components of conserved molecular pathways (Tickoo and Russell, 2002). One of the first discoveries from the genome sequence was the fly homolog of the p53 tumor suppressor. Unlike mammals, flies have a single p53 gene, greatly facilitating a functional analysis since problems of redundancy are obviated (Sutcliffe and Brehm, 2004). Over two-thirds of the genes implicated in human cancers have fly counterparts, and considerable progress is being made in understanding the biology and interactions of these genes in the fly. The Homophila database, linking entries in the Online Mendelian Inheritance in Man (OMIM) database with homologous sequences in the *Drosophila* genome currently contains over 1600 associations (Reiter *et al*., 2001). Complex processes, such as insulin signaling, the control of growth, and the regulation of longevity, are all beginning to yield to genome scale analysis in the fly. Similarly, with a sophisticated nervous system, *Drosophila* is a firmly established tool for studying conserved aspects of neurobiology. Using carefully controlled behavioral paradigms, genome-wide screens for genes involved in processes as diverse as alcoholism, drug addiction, and sleep are underway. In addition, there is considerable interest in using the fly as a model for neurodegenerative disease since the identification of homologs of genes implicated in human neuropathologies. Many groups are using genetic and microarray screens to identify gene function in neurodegenerative processes with the hope of uncovering targets for drug intervention in humans. Taken together, the *Drosophila* genome sequence has opened up a range of disease states and physiological processes to a systems level analysis in the fly and promises much in terms of increasing our understanding of human biology.

Finally, among model organisms, *Drosophila* presents a unique opportunity to link information encoded in the genome sequence to chromatin structure through the banding patterns of the polytene chromosomes. Since their discovery, many hypotheses, such as "one band-one gene", have been postulated to explain the banding pattern, although no general relationship has yet been discovered between the different chromatin states of the bands and interbands. This classical problem can now be addressed by linking the genome sequence to cytological maps of polytene chromosomes and testing the association of sequence features with banding patterns. Genomics approaches in *Drosophila* also allow the analysis of chromosome structure and organization as it relates to chromatin regulation and gene expression. For example, combining expression data with the genome sequence demonstrates the existence of gene expression "neighborhoods", linked clusters of neighboring genes with similar expression profiles (Spellman and Rubin, 2002). In addition, chromatin-immunoprecipitation (ChIP) experiments with genome tiling path microarrays allow genome-wide mapping of in vivo DNA-protein interactions (Sun *et al*., 2003). The continuing application of such approaches may present the key to unlocking the elusive relationship between chromatin structure and function and the underlying genetic or genomic organization of the chromosomes.

Short Specialist Review

The Fugu and Zebrafish genomes

Greg Elgar
MRC Rosalind Franklin Centre for Genomic Research, Cambridge, UK

The Ray-finned fish, comprised primarily of teleosts, represent over half of the world's extant vertebrates and first arose about 450 million years ago (Figure 1). In 1968, Ralph Hinegardner assayed the cellular DNA content of over 200 teleost fishes (Hinegardner, 1968). Although he documented a wide range of genome sizes, the smallest belonged to the Tetraodontoid fish, or Pufferfish. His haploid measurements of 0.40 pg of DNA per cell equate to a genome size of less than 400 Mb. However, it was not until 1990 that these findings were applied to genomics, when Sydney Brenner initiated a program to characterize the Fugu genome at the sequence level (Brenner *et al*., 1993). Nine years later, *Fugu rubripes* became the second vertebrate, after human, to have its genome sequenced to draft status (Aparicio *et al*., 2002). This was a milestone in comparative genomics, because it hailed the advent of a number of whole-genome comparisons between the human genome and other vertebrates in order to identify similarities and differences in sequence that might be linked to function (*see* Article 48, **Comparative sequencing of vertebrate genomes**, Volume 3).

Besides containing a similar set of genes, Fugu genes tend to have the same intron/exon structure as their human counterparts. There are few exceptions to this, but paradoxically, where there are differences, the tiny Fugu genome contains additional introns. For example, the human *PKD1* gene contains 46 exons, whereas the Fugu gene possesses 54 (Sandford *et al*., 1997). There are also additional introns found in the Fugu dystrophin gene (Pozzoli *et al*., 2003).

Early mapping and sequencing studies sought to establish how much conservation of gene order, or synteny, could be found between Fugu and human genomes (*see* Article 20, **Synteny mapping**, Volume 3). At a time when there were very few detailed physical maps of the human genome, sequencing the more compact Fugu genome to look for candidate genes that could be mapped back to the equivalent human region was seen as a useful approach to the identification of candidate disease genes. Some early studies showed great promise (Trower *et al*., 1996), while others failed to find expected syntenic groups (Gilley *et al*., 1997), and it soon emerged that there was a high degree of regional variation.

Nevertheless, the advantages of sequencing the Fugu genome to identify genes in a region were obvious, and this was further accelerated through the use of sequence scanning approaches. This allowed very rapid analysis of the gene content of a significant portion of the Fugu genome (Elgar *et al*., 1999), providing a much more

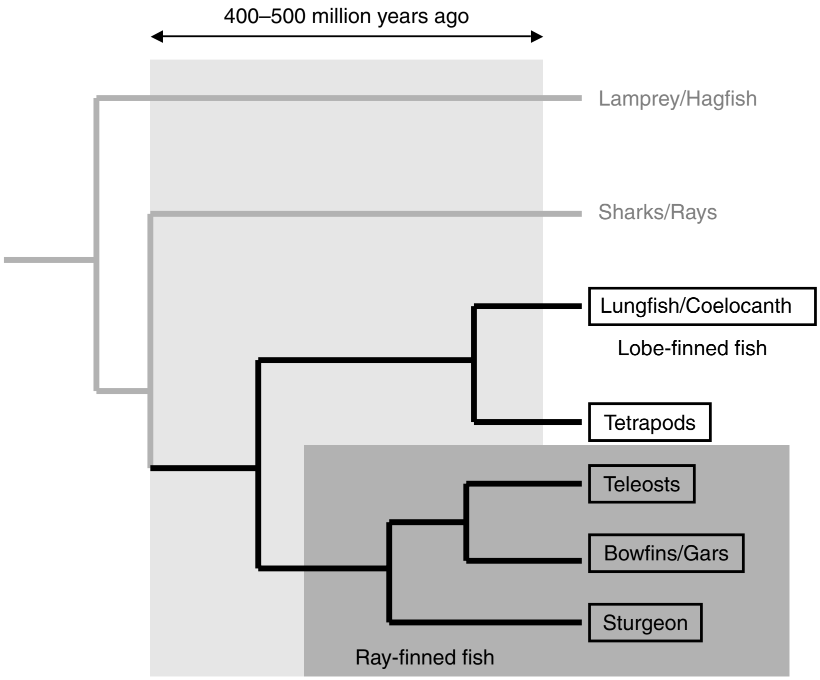

Figure 1 Schematic representation of early vertebrate evolution, indicating the relationship between tetrapods and teleost fish relative to other key orders of the fishes

detailed analysis of the structure of the Fugu genome and adding fuel to the argument for sequencing it in its entirety. In October 2000, a consortium of labs from the United States, United Kingdom, and Singapore was established to sequence the genome and 12 months later the first draft was released. Analysis of the whole-genome sequence, largely through comparison with the human genome, the only other vertebrate sequence available at the time, identified and discussed the relevance of similarities and differences between these two highly divergent genomes (Aparicio *et al*., 2002).

In support of earlier studies on smaller data sets, the Fugu genome was found to be rich in coding sequence, with small introns and short intergenic distances. Whereas the Fugu genome contains only about 500 introns greater than 10 kb in length, there are over 12 000 that exceed this size in the human genome. An exhaustive analysis of the repetitive portion of the Fugu genome found that, interestingly, although less than 15% of the genome is repetitive, a large number of different classes of repeats are identifiable. For example, there are at least 40 different families of transposable elements in the Fugu genome that have substitution rates low enough to suggest they are still active, compared to six such families in the human genome.

It is well established that the human genome has an isochore structure of low and high G+C content, which is generally reflected by regions of low and high gene density, and there is some evidence that the Fugu genome is also heterogeneous,

although not to the extent of mammals. Generally, Fugu DNA is more G+C rich than human DNA with an average across the genome of 45% compared with 41% for human. This is not simply the result of the increased density of coding sequence in the Fugu genome (which is generally much higher in G+C content) as there is little difference in average G+C between regions of very low gene density and regions of very high gene density.

A comparison of the Fugu and human proteomes provided insights into the evolution of different classes of proteins in vertebrates. While many proteins are very similar between the two genomes, about 25% of the proteome of each species is either unique or has evolved to such an extent that similarity is no longer easy to recognize using whole-genome approaches. Many of these proteins are immune related, such as cytokines, which would be expected to evolve rapidly, and more in-depth analyses have succeeded in identifying some of these, including CD4, interferons, and interleukins.

The analysis of the coding portion of the Fugu genome was made all the more difficult owing to the complete absence of cDNA data at the time. This has been redressed to an extent by another International collaboration, this time between Cambridge, Japan, and the Unites States, to sequence 24 000 ESTs, representing tags for about 10 000 Fugu genes (Clark *et al*., 2003).

With the availability of large contiguous regions, a more global assessment of synteny with mammalian genomes could be made. In agreement with many earlier reports on specific regions, the Fugu genome retains large blocks of conserved synteny with the human genome, but in general, these regions are highly scrambled due presumably to local rearrangements. Consequently, it is unusual to find more than two or three genes in the same order and orientation in both the Fugu and human genomes.

In 2004, just over two years after the analysis of the Fugu genome, the genome of a second pufferfish, *Tetraodon nigroviridis*, was released. The two genomes, unsurprisingly given their close evolutionary relationship, are remarkably similar, but importantly, as well as confirming the Fugu analysis, the Tetraodon genome data was compared with other genomes in an attempt to reconstruct the vertebrate proto-karyotype (Jaillon *et al*., 2004).

Perhaps the most exciting application of the Fugu genome in comparative genomics is in the identification, through conservation, of putative noncoding functional sequences. Early studies on the *Hox* genes demonstrated that this approach was valuable (Marshall *et al*., 1994), but once again there was some debate as to whether the Fugu genome was simply too evolutionarily distant to be of real use in this area. Nevertheless, a number of regions have been successfully identified and characterized using this approach (reviewed in Elgar, 2004).

All these regions had one thing in common; they were associated with genes involved in developmental regulation. Capitalizing on this, Woolfe *et al*. (2005) carried out a genome-wide survey of all highly conserved noncoding sequences in Fugu, examined their association with genes involved in development, and critically developed an assay that allowed these sequences to be functionally annotated. With a hint of irony, the organism that they used to functionally assay these highly conserved sequences was the zebrafish.

Whereas the motivation behind sequencing the Fugu genome derived solely from the need for a model organism for comparative genomic analyses, the need to sequence the zebrafish genome was driven by researchers already using the zebrafish as an experimental model in its own right. The Fugu genome may be small but as an experimental system it is far from ideal. These pufferfish are large marine teleosts that take two to three years to reach sexual maturity and only produce eggs and sperm seasonally. They are not suited to tank breeding and are expensive to maintain.

The zebrafish on the other hand, emerged primarily because of its advantages as an experimental system. It is a common, freshwater aquarium fish that is extremely easy to keep and maintain at relatively high densities. They are small (adults are about 3 cm in length) and reach sexual maturity at about 12 weeks. Moreover, and perhaps most importantly, they readily generate large numbers of fertilized eggs. Collection of newly fertilized eggs can be coordinated ready for injection/manipulation using a fixed light cycle. While being oviparous has clear advantages for observation of the developing embryo, the zebrafish has the added benefit that the embryo is virtually transparent. In fact, providing it is not permitted to dry out, an embryo will develop normally while being observed under a microscope.

As a result, the zebrafish genome was prioritized by the genomics community, and more importantly, by the funding agencies, as one of the key genomes to be sequenced after the human genome. Unfortunately, the zebrafish genome is rather large for a teleost fish, with an estimated size of between 1600 and 1700 Mb, making it four to five times larger than the Fugu genome. An additional difficulty associated with the whole genome shotgun assembly is that the DNA was derived from a thousand embryos, resulting in a very high level of polymorphism within the source DNA. Robust draft assemblies, tied to fingerprint maps, started to appear in 2003 with an estimated completion date of 2005. While its genome is not yet as complete as that of Fugu, there are both genetic linkage maps (Knapik *et al*., 1998; Hukriede *et al*., 1999) and radiation hybrid panels (Gates *et al*., 1999; Kelly *et al*., 2000) available for zebrafish, and in addition there is a large community of experimental biologists working on its biology. A large number of ESTs have also been sequenced, and as a result, the development of comprehensive zebrafish microarrays is well under way (Lo *et al*., 2003). The zebrafish is from the Ostariophysi, whereas the pufferfish are from the Acanthopterygii. While lack of fossil records makes it difficult to date this divergence, these two Superorders diverged very early in the teleost radiation, at least 100–150 and possibly over 200 million years ago. From an evolutionary point of view, the relative positions of these two fish are extremely fortuitous, as they are divergent enough to make genomic comparison informative, while capturing a significant proportion of teleosts between them. Consequently, if gene order across a region is conserved between Fugu and zebrafish, it is likely that it will also be syntenic in other teleost fish. The combination of genomics and experimental biology using these two fish provides some exciting opportunities and has already been used in order to dissect the regulatory region of the *SCL* gene (Barton *et al*., 2001).

With the sequence data generated from both the Fugu and zebrafish genomes, a pattern of genome duplication within the teleost lineage is emerging. This duplication must have been early to have occurred in both genomes and it is

now thought that the duplication might have been formative in the evolution of the teleost lineage itself (Taylor *et al*., 2003). This results in both zebrafish and Fugu genomes having a number of additional copies of genes, although it is not clear how many. A best guess estimate for the Fugu genome would be that it has retained about 10% of its duplicates, whereas this figure might be closer to 15% for the zebrafish. Further comparative analyses with the completed zebrafish genome should provide a more accurate estimate.

The Fugu and zebrafish genome sequences follow closely on the heels of the human genome and have provided templates for a variety of comparative analyses encompassing both coding and noncoding DNA. The completion of the zebrafish genome will not only improve the power of this form of analysis, but will also provide a tremendously valuable resource for the zebrafish experimental community.

Short Specialist Review

The mouse genome sequence

Ian J. Jackson
Western General Hospital, Edinburgh, UK

The mouse, having long been established as the leading mammalian genetic model system (*see* Article 38, **Mouse models**, Volume 3), was highlighted early in the Human Genome Program as a priority candidate for genome sequencing. In 2002, a publicly funded consortium published a high-quality draft sequence from the mouse strain C57BL/6J (Mouse Genome Sequencing Consortium, 2002), which has become the reference sequence. The sequence was available via the Internet and utilized by many well before its publication. Publication of this sequencing effort was preceded by (and may well have been accelerated by) a commercial pay-for-use sequence that was a combination of a number of different strains (some data discussed in Mural *et al*., 2002).

The public effort used a whole genome shotgun (WGS) methodology, albeit integrated with a deep Bacterial Artificial Chromosome (BAC) contig (Gregory *et al*., 2002) by inclusion of the ends of these BACs in the shotgun assembly. The sequence could also be linked to high-resolution genetic maps through the BAC contig and through the many sequenced molecular markers used in the mapping. In recognition of the importance of the mouse genome, efforts continued in order to generate finished sequence from individual mouse BAC clones. The use of a WGS methodology led to the omission of some segmental duplications from the draft sequence, which have "collapsed" to single copy, or have been omitted from the assembly (Cheung *et al*., 2003; Bailey *et al*., 2004). Nevertheless, it appears that the mouse genome has less segmental duplication than the human sequence; 1–2% compared to 5–6% in humans.

The mouse genome sequence has considerable value in three areas:

- to facilitate the identification of the molecular basis of variation and mutation, principally through the identification and localization of genes in the sequence;
- as a means of discovering gene regulation and other control elements in the genome, by comparison with other vertebrate sequences;
- as a model for understanding the evolution of genomes.

Gene predictions using the draft sequence produce an estimate of mouse gene number of around 30 000, very similar to the human gene number (Mouse

Genome Sequencing Consortium, 2002; International Human Genome Sequencing Consortium, 2001). Not surprisingly, the vast majority (99%) of predicted mouse genes have homologs in the human genome. Perhaps more surprising is that only around 80% of mouse genes have clear 1:1 orthologs in the human sequence; that is, where a mouse gene has only a single human ortholog and vice versa. The absence of 1:1 orthology for so many genes is largely due to differential expansion of gene families in different species. Comparison with the rat genome sequence shows that substantial differential expansion has occurred even within the rodent lineage (Rat Genome Sequencing Project Consortium, 2004). Analysis of the function of gene families that have expanded in the mouse relative to humans suggests that the expansions have occurred through selection imposed by mouse- or rodent-specific lifestyles or behaviors. Thus, the mouse repertoire of olfactory receptors is greatly expanded relative to humans, although the receptor structures seem to cover the same range. The many more mouse receptors perhaps indicate that mice can better discriminate between closely related scents (Zhang and Firestein, 2002). Mice appear also to have expanded gene families, relative to humans, that encode certain reproductive functions, and others that are involved in innate immunity. The large cytochrome P450 gene family also shows numerous differences between mouse, humans, and rats, most likely because the toxin-metabolizing enzymes encoded by this family have been differentially selected in different species.

A high-quality genome sequence has greatly accelerated the identification of genes that are responsible for mouse mutant phenotypes (*see* Article 38, **Mouse models**, Volume 3). Before the sequence was available, the so-called positional cloning required that the candidate interval containing the mutation be reduced as much as reasonably possible by genetic mapping crosses. Mutation identification, now that the sequence is on hand, can begin with a lower resolution genetic cross from which all candidate genes in the interval can be identified and sequenced in the mutant strains. The much lower cost, and higher speed, of sequencing relative to animal husbandry has led to mutant gene identification using many fewer animals, which is an important animal welfare spin-off from the genome sequence.

A comparison of sequence from multiple inbred mouse strains shows that sequence differences between strains are not uniformly distributed across the genome (Wade *et al*., 2002). Instead, any pair of strains has large regions that have nucleotide differences (mainly single base differences) at an average rate of 1 per 250 bp, while other regions differ at only one base in 20 kb. Furthermore, comparison between any two strains will show a different genomic distribution of high and low variation than another pair. The laboratory mouse is a mixture of two subspecies of *Mus musculus*, *M. m. domesticus* and *M. m. musculus*. The distribution of variation probably reflects the origin of each genomic region within the strain; high variation being intersubspecific and low variation, intrasubspecific. One difference in 20 kb is a rather low level of intrasubspecies variation, when compared to the variation seen in other populations, such as humans, and probably reflects the small founder population of laboratory mice. This simplistic model leads to the hypothesis that much of the complex genetic diversity of phenotype between strains is due to their mosaic of subspecies origins. It may be possible to narrow the genomic interval containing particular Quantitative Traits Loci (QTLs) by comparing the pattern of sequence variation between multiple strains. A model

experiment that compared albino with pigmented strains has demonstrated that this approach can home in on within a few hundred kilobases of the tyrosinase gene, the gene that is known to cause the albino phenotype.

About 1.5% of the genome is coding sequence of genes and another 1% represents untranslated sequences of mRNA. When the mouse genome sequence is compared to the human sequence, about 5% aligns better than would be expected for a sequence that has randomly mutated over evolutionary time, and hence appears to be under selection. The excess of selected sequence over gene sequences probably consists of transcriptional and other regulatory elements (Dermitzakis *et al*., 2002). Comparison of the mouse and human with additional genomes gives more specificity to the comparison and is able to select potential regulatory regions. As an example of the utility of sequence comparisons, the mouse, human, and Fugu sequence around the *Pax6* locus has been compared and potential long-range regulatory elements identified. By generating transgenic mice in which these elements have been linked to reporter genes, Kleinjan *et al*. (2001) have demonstrated that they do indeed have regulatory potential.

As species have diverged during evolution, their respective genomes have undergone large-scale alterations, so that their gene content and gene order may stay roughly the same at a megabase scale, but at a larger, chromosomal scale there has been rearrangements of genomic segments. A comparison between the mouse and human genomes shows that there have been about 300 chromosomal rearrangements during the 75 million years of evolution that separated these species (Mouse Genome Sequencing Consortium, 2002). When the rat genome is analyzed in addition, it can be seen that the rate of rearrangement in the rodent lineage overall is much greater than in the evolutionary path to humans (Rat Genome Sequencing Project Consortium, 2004). When the rate of neutral sequence base changes is examined in these same lineages, it too is about twice as fast in the path to rodents than that to humans from their last common ancestor. Possibly, a more rapid generation time in rodents and their ancestors has resulted in more sequence changes when measured against time.

Like other sequenced mammalian genomes, a substantial fraction of the 2500 Mb of the mouse genome is made up of repetitive DNA. Most repetitive DNA is derived from transposable elements that have spread throughout the genome at various points in evolution. These transposons spread by multiplication of individual elements, which means that they can be categorized on the basis of their sequences into families. Comparison with the rat and human genomes allows these families to be classified as mouse specific, rodent-lineage specific, and ancestral; the last group being sequences that can be recognized as shared between all three mammals and must have been present in their last common ancestor (Mouse Genome Sequencing Consortium, 2002; Rat Genome Sequencing Project Consortium, 2004). About one-third of the mouse genome is made up of repetitive DNA that arose since humans and rodents diverged, of which about 350 Mb, or 14% of the total, is specific to the mouse lineage. Only about 5% of the genome is recognizable as ancestral repetitive DNA, apparently a much smaller fraction than the 22% seen in the human genome. However, the more rapid rate of sequence changes in the rodent lineage has probably caused the drift of ancestral sequences so that they are no longer recognizable.

In summary, the mouse genome is about 14% smaller than that of humans, although it has about the same gene content. Almost all of the 30 000 genes have orthologs in humans. The smaller DNA content of the mouse genome is not due to less-active recent transposition of repetitive sequences; in fact, there has been more activity in the mouse. Rather, there has been more deletion of nonfunctional DNA in the rodent lineage, which has removed ancestral as well as recent repetitive DNA.

The utility of the genome sequence has already been demonstrated many times by geneticists who have used it in the identification of genes underlying mutant or variant phenotypes. As more mammalian genomes are sequenced, the power of comparative genomics becomes more apparent, and a high-quality finished sequence should further promote the mouse as the principal mammalian model organism.

Short Specialist Review

Comparative sequencing of vertebrate genomes

Matthew E. Portnoy and Eric D. Green
National Human Genome Research Institute, Bethesda, MD, USA

1. Introduction

The past decade has brought astonishing growth in the generation of sequence data from eukaryotic genomes. This has largely been catalyzed by major technological and strategic advances in large-scale DNA sequencing (Green, 2001a), coupled with the intense effort to complete the Human Genome Project (*see* Article 24, **The Human Genome Project**, Volume 3) and, in particular, to finish the sequence of the first vertebrate genome – that of *Homo sapiens* (International Human Genome Sequencing Consortium, 2001; Venter *et al*., 2001).

With a complete human genome sequence now available, attention has rapidly turned to understanding the functional information it encodes. Significant advances have been made in identifying the protein-coding portion of the human genome (International Human Genome Sequencing Consortium, 2001; Venter *et al*., 2001); however, this portion only reflects an estimated 1–2% of the ∼2.9-Gb human genome sequence. Importantly, an additional 3–4% of the human genome appears to be functional, but does not code for protein (Mouse Genome Sequencing Consortium, 2002; Rat Genome Sequencing Project Consortium, 2004); these sequences include elements that provide temporal and spatial control of gene expression (Wasserman and Sandelin, 2004) as well as those involved in chromosome dynamics. It is now apparent that a comprehensive cataloging of all functional elements in the human genome, especially those that do not directly code for protein, will require a multifaceted approach, involving the generation of additional laboratory- and computational-based data and the development of new paradigms for assimilating and analyzing the resulting complex data sets.

One of the most powerful approaches for identifying functional genomic elements involves the comparison of genome sequences from species at distinct evolutionary positions (Miller *et al*., 2004; Nobrega and Pennacchio, 2004; Boffelli *et al*., 2004; Pennacchio, 2003; Hardison, 2003). The resulting information provides a working knowledge of the precise sequence-level similarities and differences among genomes, which in turn can be used to gain insight about genome function. For example, sequences found to be common (or conserved) among species separated by large evolutionary distances (e.g., >50–100 million years) can be

considered candidates for serving a functional role; the process of identifying such conserved sequences has been termed *phylogenetic footprinting* (Duret and Bucher, 1997; Weitzman, 2003). In contrast, sequences found to be different among closely related species (e.g., primates) can be considered less likely to be functional; the process of "eliminating" such sequences from consideration (thereby leaving the remaining sequences as candidates for serving a functional role) has been termed *phylogenetic shadowing* (Boffelli *et al*., 2003; Boffelli *et al*., 2004). In short, strategies have emerged that involve the use of genome sequences from both closely and distantly related species to extract functional information by comparative sequence analysis.

Two complementary approaches have been used in recent years to generate vertebrate genome sequences (Green, 2001a) en route to comparative analyses. In whole-genome sequencing projects, data are generated across an entire species' genome (International Human Genome Sequencing Consortium, 2001; Venter *et al*., 2001; Mouse Genome Sequencing Consortium, 2002; Aparicio *et al*., 2002; Rat Genome Sequencing Project Consortium, 2004); while such efforts are comprehensive with respect to the individual genome, they are limited in terms of the total number of different genomes that can be compared (because of the costs associated with sequencing an entire vertebrate genome). A subset of the whole-genome sequencing projects performed to date has involved species that are used as experimental models (the so-called reference genomes, such as mouse, rat, and zebrafish; *see* Article 39, **The rat as a model physiological system**, Volume 3, Article 46, **The Fugu and Zebrafish genomes**, Volume 3, and Article 47, **The mouse genome sequence**, Volume 3, respectively). In targeted sequencing projects, data are generated for discrete genomic regions, typically from multiple species (Thomas *et al*., 2003); while such efforts examine only a limited portion of the genome, they result in sequence comparisons that involve large collections of evolutionarily diverse species. The major vertebrate whole-genome and targeted sequencing efforts are listed at **www.intlgenome.org**.

2. Vertebrate whole-genome sequences

The central goals of the Human Genome Project included the generation of foundational information about the human genome and that of a handful of carefully selected other species, in particular, commonly used experimental models (Green, 2001b; *see also* Article 24, **The Human Genome Project**, Volume 3). Initially, only human and mouse were included among the vertebrates, but more recently that list has grown substantially (Table 1).

A finished human genome sequence was generated using a clone-based shotgun-sequencing strategy (International Human Genome Sequencing Consortium, 2001; *see also* Article 3, **Hierarchical, ordered mapped large insert clone shotgun sequencing**, Volume 3), whereby minimal overlapping sets of large-insert clones (mostly bacterial-artificial chromosome (BAC) clones) were individually subjected to random shotgun sequencing, followed by directed finishing (Green, 2001a). The prior construction of a BAC-based physical map of the human genome (McPherson

[a]HSS = clone-based hierarchical shotgun sequencing (*see* Article 3, **Hierarchical, ordered mapped large insert clone shotgun sequencing**, Volume 3); WGS = whole-genome shotgun sequencing.
[b]Sequence coverage indicated as redundant coverage (e.g., 4X) or percent of total covered by assembled sequence (e.g., 99%).

et al., 2001) provided a key organizing framework for the long-range assembly of the whole-genome sequence.

Sequencing the genome of the most widely used experimental mammal – the laboratory mouse – began prior to completion of the Human Genome Project (Table 1; *see also* Article 47, **The mouse genome sequence**, Volume 3). The initial phase of this effort involved whole-genome shotgun sequencing and initial assembly (Mouse Genome Sequencing Consortium, 2002), with BAC-based finishing now ongoing. The mouse's critical role in biomedical research has prompted the finishing of its genome sequence to roughly the same quality as the completed human genome sequence. Interestingly, initial comparisons reveal that roughly 40% of the mouse genome sequence aligns with the corresponding (or orthologous) regions of the human genome sequence (Mouse Genome Sequencing Consortium, 2002), but only a small minority of that aligning sequence (totaling roughly 5% of the mouse or human genome) is actively conserved and presumed to be functionally important.

The third mammalian whole-genome sequence to be generated was that of the rat (Rat Genome Sequencing Project Consortium, 2004) (Table 1). This project

utilized an integrated whole-genome and BAC-based shotgun-sequencing strategy, which yielded a very high-quality draft sequence. However, at present, there are no plans to finish the rat genome sequence to the same quality standards as were used for the human or mouse genome sequences. Indeed, until the costs of sequence finishing decrease substantially, it is unclear which other vertebrate genomes (if any) will be sequenced as accurately and completely as the human genome.

Whole-genome draft sequences have also been generated for a trio of fish species: zebrafish (*Danio rerio*) and two types of pufferfish, *Fugu rubripes* (Aparicio *et al*., 2002) and *Tetraodon nigroviridis* (Table 1) (*see* Article 46, **The Fugu and Zebrafish genomes**, Volume 3). The zebrafish genome sequence will be critical for the rapidly growing research community using these fish as experimental models, whereas the two pufferfish species were selected for their notably compact genomes (among the smallest of all vertebrates). Among the primates, a whole-genome draft sequence has been generated for the chimpanzee, our closest relative in evolution, while that of the rhesus macaque is actively being produced. The current list of available or planned vertebrate whole-genome sequences includes that of two additional nonprimate eutherian mammals (dog and cow), a marsupial (the laboratory opossum *Monodelphis domestica*), a bird (the chicken), and an amphibian (the frog *Xenopus tropicalis*) (Table 1). As the costs of large-scale DNA sequencing decline, the list of generated vertebrate whole-genome sequences (such as in Table 1) will inevitably grow, with the strategies for generating and analyzing that sequence likely changing as well (see below).

The generation of an ever-growing set of vertebrate genome sequences, coupled with initial efforts to compare them in a rigorous fashion, has yielded spectacular amounts of data. To ensure that this information is readily accessible and comprehensible, especially to the general biomedical research community, several groups have developed "genome browser" systems. These consist of convenient navigational tools for accessing and utilizing the genomic sequence of different vertebrates as well as organized frameworks for assimilating relevant annotations, including those emanating from comparative analyses. The three most widely used genome browsers are the UCSC Genome Browser (**genome.ucsc.edu**), Ensembl (**www.ensembl.org**), and NCBI Map Viewer (**www.ncbi.nlm.nih.gov/mapview**). As a representative example, Figure 1 depicts a ∼150-kb segment of the human genome, as displayed by the UCSC Genome Browser. Note the ability to observe simultaneously the structure of known genes in the region (*RET* and *GALNACT-2*) as well as various other types of information (e.g., promoters, repetitive elements, and the results of comparative analyses with a handful of other species). Indeed, this figure illustrates how genomes will likely be viewed in the coming years, as increasingly detailed information about genes, other functional elements, regions of sequence conserved among various species, and other genome features of interest are assimilated layer by layer.

3. Multivertebrate sequences of targeted genomic regions

While the above whole-genome sequencing efforts are providing valuable data for comparative analyses, they are limited in the total number of vertebrates being

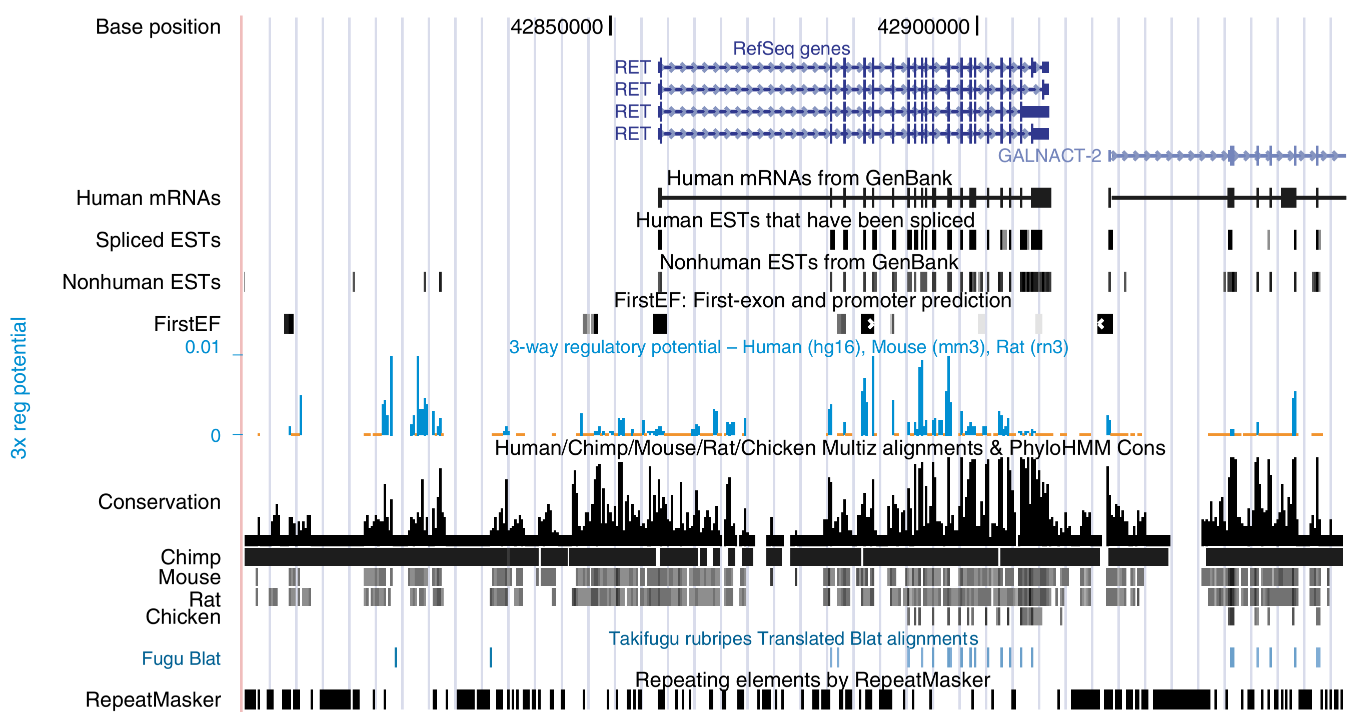

Figure 1 View of a roughly 150-kb segment of the human genome, as displayed on the UCSC Genome Browser. A segment of human chromosome 10 encompassing the *RET* gene is shown (July 2003 build of the human genome sequence, UCSC version hg16/NCBI build 34; coordinates chr10:42,800,001-42,950,000). Various annotations are displayed; in particular, note the tracks depicting the results of comparative sequence analyses (see **genome.ucsc.edu** for details)

studied (see Table 1). To complement these projects, the sequence of smaller, targeted genomic regions can be generated from a greater number of species, resulting in comparative sequence analyses with larger, more evolutionarily diverse collections of vertebrates (Thomas and Touchman, 2002). For example, the NISC Comparative Sequencing Program (see **www.nisc.nih.gov**) is currently sequencing more than 150 targeted regions of the human genome in multiple vertebrates, in some cases generating orthologous sequence data from over 30 species (Thomas *et al*., 2003).

These studies have already yielded some interesting findings. First, the resulting data have reflected the first-available genomic sequence for a number of vertebrates, providing new insights about the genetic blueprints of these species. These have included information about gene density, the relative degree of genome compression/expansion, the amounts and types of repetitive sequences, the extent and types of mutational events that have uniquely sculpted each genome, and the general patterns of conservation seen upon comparison with other species' sequences (Thomas *et al*., 2003). Second, the generation of orthologous sequences from large sets of vertebrates has catalyzed the development of computational methods for multispecies comparative sequence analyses. For example, new approaches have been developed for identifying sequences that are highly conserved across multiple species (called *Multispecies Conserved Sequences* or *MCSs*) (Margulies *et al*., 2003; Margulies *et al*., 2004). Interestingly, vertebrates differ with respect to the effectiveness of their sequence for detecting MCSs in the human genome (Margulies *et al*., 2003; Margulies *et al*., 2004). Finally, targeted sequencing projects are particularly well suited for genome-evolution studies because they can readily yield sequence data from carefully selected species of interest (Thomas *et al*., 2003). Such studies can include in-depth surveying of multiple species at a particular phylogenetic node (e.g., primates), which, at least for the foreseeable future, is not possible with whole-genome sequence data sets.

Multivertebrate sequencing of targeted genomic regions is playing an important role in the recently launched ENCODE (Encyclopedia of DNA Elements) project, which aims to identify all of the functional elements in the human genome (**genome.gov/ENCODE**). ENCODE's initial goal is to catalog comprehensively the functional elements in a selected 1% (~30 Mb) of the human genome, using a diverse set of experimental and computational approaches. These targeted ~30 Mb, which are distributed across 44 different genomic regions, are being sequenced in multiple vertebrates. The resulting sequences will be subjected to myriad comparative analyses, with the results in turn compared to various other types of data (computational and experimental) generated for the same ~30 Mb. Eventually, this process should provide important insights into the utility of multispecies sequence comparisons for unraveling the complexities of genome function.

4. Deducing genome function through sequence comparisons

Comparative analyses of whole-genome and targeted-genome sequences from various vertebrates have been shown to be valuable for the study of genome function. Simple alignments of orthologous sequences from two or more genomes

can be used to identify the presence and structure of genes (Batzoglou *et al*., 2000; Miller *et al*., 2004). More refined approaches have been developed for gene prediction that involve sequence comparisons; for example, using the human and mouse genome sequences, TWINSCAN (Korf *et al*., 2001) and SLAM (Alexandersson *et al*., 2003) have been used to produce a conservative estimate of 25,622 genes in the human genome (Flicek *et al*., 2003) and to detect roughly 80% of the predicted human exons in the NCBI RefSeq gene collection (see **www.ncbi.nlm.nih.gov/RefSeq**) (Alexandersson *et al*., 2003). In a more targeted fashion, human–mouse sequence comparisons directly led to the discovery of the apolipoprotein A5 gene (*APOA5*) (Pennacchio *et al*., 2001); subsequent functional studies showed the importance of *APOA5* in regulating triglyceride levels (Pennacchio, 2003).

Comparative sequence analyses are also proving critical for detecting conserved sequences outside of coding regions, which are candidates for functional noncoding elements (e.g., such as those regulating gene expression). For example, phylogenetic footprinting of sequences from a set of diverse mammals identified several regulatory elements upstream of the ε-globin gene (Gumucio *et al*., 1993). Similarly, human–mouse sequence comparisons of the interleukin gene cluster identified several conserved noncoding sequences, the longest of which was shown to be a cis coactivator of several nearby interleukin genes (Hardison, 2000; Loots *et al*., 2000). More global methods have now been developed for identifying sequences that are most highly conserved across multiple species (Margulies *et al*., 2003; Dermitzakis *et al*., 2003), many of which are likely to be functionally important. Interestingly, in the human genome, there are more such highly conserved sequences within noncoding regions compared to coding regions (Margulies *et al*., 2003; Margulies *et al*., 2004). By a different strategy (specifically, phylogenetic-shadowing methods), sequence comparisons involving closely related species have been used to identify potential regulatory elements (Boffelli *et al*., 2003; Boffelli *et al*., 2004).

5. Future prospects

The landscape of comparative vertebrate sequencing is changing rapidly. The major commitments to date for whole-genome sequencing mostly involve vertebrates associated with large research communities that will directly exploit the resulting sequence data. As such, the genome sequences of species such as human (International Human Genome Sequencing Consortium, 2001; Venter *et al*., 2001), mouse (Mouse Genome Sequencing Consortium, 2002), rat (Rat Genome Sequencing Project Consortium, 2004), chicken, zebrafish, *Xenopus*, dog, and cow provide reference information of great value. In addition, each whole-genome sequence provides secondary value by contributing to an ever-expanding repertoire of comparative sequence analyses, which more broadly advance our knowledge of complex genomes. However, only a few remaining vertebrates can be regarded as true reference species, and thus a primary rationale for most future genome-sequencing projects will be the acquisition of data for comparative studies.

The current plans for vertebrate genome sequencing largely reflect these changing priorities. Ongoing or soon-to-be-initiated sequencing projects include a wider

sampling of vertebrates across the phylogenetic tree and exploration of a larger set of primates. Significantly, recent findings indicate that the identification of highly conserved sequences from evolutionarily diverse species can be accomplished with lower-quality draft sequence. Specifically, comparative analyses using low-redundancy genomic sequences (e.g., providing one- to twofold coverage) from a larger number of species appear to be more effective in identifying the most highly conserved genomic elements than those using high-redundancy sequences (e.g., providing two- to fourfold coverage) from a smaller number of species (unpublished data). These findings are prompting efforts to acquire low-redundancy genomic sequence from a large, diverse group of vertebrates. Such an endeavor would not be for the purpose of generating an assembled sequence of each genome but rather to amass a large data set that can be used predominantly for comparative analyses. This approach reflects a strategic shift from the sequencing projects performed under the auspices of the Human Genome Project, but one that resonates with the high-priority efforts to interpret the human genome sequence in a comprehensive fashion.

More futuristic views of comparative vertebrate sequencing largely depend on the knowledge of the relative costs of large-scale DNA sequencing. Should those costs continue to decline substantially, then the genomes of much larger collections of vertebrates (and indeed invertebrates as well) would inevitably be sequenced, with the resulting massive data sets greatly empowering comparative studies. Regardless, the lessons learned to date clearly indicate that the sequence of each species' genome contains a treasure trove of information about evolutionary history and that comparisons of those histories are critical for understanding the complexities of genome structure and function.

Acknowledgments

We thank Elliott Margulies, Bob Blakesley, Nancy Hansen, and Monica Janossy for the critical reading of this chapter.

Short Specialist Review

The chimpanzee genome

Tarjei S. Mikkelsen
Broad Institute of MIT and Harvard, Cambridge, MA, US

1. Introduction

As our closest, extant evolutionary relative, the common chimpanzee (*Pan troglodytes*) offers a unique perspective on the human species and its history. All heritable, biological traits unique to our species, such as distinct anatomy, cognitive capacities, and some disease susceptibilities are ultimately caused by one or more discrete differences between the human and chimpanzee genomes. Comparative analysis can help reveal these differences, as well as the mutational processes and selective pressures that have generated them.

An initial draft sequence of the chimpanzee genome, based on 4x whole-genome shotgun (WGS) coverage (*see* Article 4, **Sequencing templates – shotgun clone isolation versus amplification approaches**, Volume 3) of a single donor, has been made publicly available by a US-based consortium (Chimpanzee Sequencing and Analysis Consortium, 2005). Additional WGS sequencing, as well as efforts to construct a BAC-based physical map, are underway. The draft WGS sequence assembly is supplied with nucleotide quality scores indicating the presence of potential sequencing errors (*see* Article 11, **Algorithms for sequence errors**, Volume 7), which are particularly important to take into account when comparing closely related species.

A growing number of additional genomic resources are also available, including a BAC-based assembly of chromosome 21 (formerly chromosome 22; McConkey, 2004) from a different individual (Watanabe, 2004); two chromosome Y sequences (Hughes *et al*., 2005; Kuroki, 2006); PCR amplified exons from over 13,000 known genes (Nielsen, 2005); cDNA sequences (Hellmann, 2003); and light WGS coverage of additional West African and Central African chimpanzees (Chimpanzee Sequencing and Analysis Consortium, 2005).

2. Magnitude and patterns of sequence divergence

Because of the relatively short time since the divergence of humans and chimpanzees, most nucleotides in our genomes are identical by descent, and an observed difference nearly always represents a single mutation. Most of the differences reflect random genetic drift, and thus they hold extensive information

about the mutational processes that have shaped our genomes in recent evolutionary history.

Single nucleotide substitutions are the most abundant type of differences. Overall, 1.23% of orthologous nucleotides differ, of which 85% or less represent fixed interspecies divergence, and the rest are due to intraspecies polymorphism. Substitutions are not uniformly distributed throughout the sequences, largely reflecting context-dependent variation in mutation rates. For example, although CpG dinucleotides constitute only 2% of the genomes, they account for a quarter of all nucleotide substitutions. On a larger scale, orthologous sequences situated within 10 Mb of a telomere have, on average, accumulated 15% more substitutions than the rest of the genome.

Nucleotide insertions and deletions (indels) are less abundant than substitutions, but affect significantly more sequence overall. In total, 5 to 6 million indels have resulted in the human and chimpanzee genomes each containing 40 to 45 Mb of euchromatic sequence not present in the other. The vast majority of indels are small (98.6% are shorter than 80 bp), but the largest few contain most of the affected sequence (approximately 70000 indels longer than 80 bp constitute 75% of the linage-specific sequences).

Transposable elements are the source of distinct indels in both the human and chimpanzee genomes. The major difference is the emergence of large, subterminal caps of satellite repeats on chimpanzee chromosomes (Yunis and Prakash, 1982). The euchromatic sequences also show evidence of linage-specific insertions of all major classes of transposable elements. The primate-specific Alu element has been three-fold more active in the human genome, whereas LINE-1 elements have been inserted at similar rates in both genomes. Transposable element insertions may have affected expression or splicing patterns of nearby genes (Britten, 1997).

Large-scale chromosomal rearrangements make up the least abundant, but most dramatic, differences between the two genomes. Early cytogenetic characterization revealed 9 pericentric inversions between human and chimpanzee chromosomes and a fusion of two ancestral chromosomes in the human lineage (Yunis and Prakash, 1982). Surveys of structural variation aided by the WGS assembly have refined the localization of these rearrangements, and revealed several hundred additional chromosomal inversions, segmental duplications and deletions (Newman *et al*., 2005). A significant fraction overlap known genes, and have consequently contributed to differences in expression levels of these genes between the two species.

3. Signatures of natural selection

Mutations provide the substrate upon which natural selection acts to mould the evolution of a species. The impact of natural selection can be inferred from patterns of sequence divergence that deviate from those expected under neutral drift (*see* Article 9, **Modeling protein evolution**, Volume 1).

Signatures of negative selection, or removal of deleterious alleles from a population, are easily recognizable by comparing orthologous genes in humans and chimpanzees. The average protein coding gene has accumulated only a single

amino acid substitution in each of the human and chimpanzee lineages since our divergence, and the mean ratio of nonsynonymous to synonymous substitutions across all orthologs is 0.23, indicating that at least 77% of amino-acid changing mutations are sufficiently deleterious to be removed by natural selection. This ratio is approximately 35% higher than observed between mouse and rat orthologs, indicating a general relaxation of evolutionary constraints in the primate lineages relative to the murid lineages, likely due to smaller effective population sizes, and consequently a greater impact of genetic drift, in humans and chimpanzees.

Signatures of positive selection, or rapid fixation of advantageous alleles, are more challenging to detect, but of even greater interest. Although effectively neutral alleles may well have phenotypic effects, it is generally thought that signatures of positive selection can help pinpoint the genetic changes most critical to our evolutionary history. The low divergence rates between human and chimpanzee orthologs greatly limit the power of statistical test for positive selection in any single gene. Grouping genes into relevant categories, such as cellular function or pathway membership, can increase statistical power at the cost of lower resolution. Orthologs involved in the immune- and reproductive systems dominate the categories showing an excess of nonsynonymous over synonymous substitutions, the most stringent test for adaptive selection. This is a common observation in higher organisms studied so far, reflecting sustained selective pressures on these systems throughout evolution.

Lineage-specific acceleration of rates of evolution can reveal more subtle signatures of positive selection. Accounting for the overall relaxation of constraints in primates, the rates of evolution of primate and murid orthologs are highly correlated, but there is detectable acceleration in some functional groups. Genes involved in spermatogenesis and the male reproductive system show the most significant primate-specific acceleration, potentially reflecting a particularly strong influence of sexual selection on primate evolution. There is significantly less evidence of lineage-specific acceleration between human and chimpanzee orthologs when the murid genomes are used as outgroups, reflecting more similar selection pressures within the primate lineages. But, notably, the functional category that shows the strongest acceleration in the human, compared to the chimpanzee, is the transcription factor, supporting the hypothesis that changes in gene regulation may be a key factor underlying rapid anatomical evolution in the human lineage (King and Wilson, 1975).

4. Applications and prospects

There is much to be learned from comparison of the human and chimpanzee genome sequences beyond what has been gleaned from initial surveys.

The chimpanzee genome sequence has a special role in informing studies of human population genetics (*see* Article 1, **Population genomics: patterns of genetic variation within populations**, Volume 1). In particular, it was used to validate novel single nucleotide polymorphisms (SNPs) for a human haplotype map (International HapMap Consortium, 2005). The sequence can also be used to estimate regional mutation rates, and as an effective outgroup to classify segregating alleles in the human population as ancestral or derived. The initial WGS assembly

facilitated assignment of ancestral states to over 80% of all publicly available SNPs mapped to the human genome with 98% accuracy. High resolution maps of local mutation rates and ancestral allele assignments can be used to directly inform inferences about genetic drift and natural selection in recent human history (Article 7, **Genetic signatures of natural selection**, Volume 1).

In addition to informing scans for recent selection in anatomically modern human populations, comparative analysis of primate genomes provides a unique opportunity for elucidating the evolutionary history of the human and Africa great ape lineages close to the times of divergence. The chimpanzee genome likely holds important clues to the extent of gene flow and the mechanisms that generated reproductive barriers between our progenitor populations, as well as the pace and extent of adaptive evolution following speciation.

Most initial analyses of evolution and selection in the human and chimpanzee lineages have focused on protein coding sequences, and largely ignored other functional elements in the genomes. Progress in comparative genomics (*see* Article 48, **Comparative sequencing of vertebrate genomes**, Volume 3) and growing appreciation of the abundance and importance of *cis-regulatory* elements and noncoding RNA in mammalian genomes (*see* Article 27, **Noncoding RNAs in mammals**, Volume 3) is rapidly removing this bias. The chimpanzee genome sequence allows systematic analysis of recent evolution in noncoding sequences and their effects on gene expression and development. For example, the sequence can be used to design gene expression assays suitable for cross-species comparisons with hybridization probes specific to sequences that do not differ with human, or alternatively, to mask unsuitable probes on existing human microarrays.

The ultimate goal of the chimpanzee genome project is to identify the specific genetic alterations that underlie each phenotypic difference between humans and other primates. This is made particularly challenging by the practical and ethical limitations on any experimental investigation, but careful correlation of genetic differences with phenotypic and clinical data is contributing to a growing list of genotype-phenotype relationships (Varki and Altheide, 2005).

Short Specialist Review

Functional annotation of the mouse genome: the challenge of phenotyping

Steve D. M. Brown
MRC Mammalian Genetics Unit, Harwell, UK

1. Functional annotation of the mammalian genome

With the completion of the human genome sequence, attention has turned to the functional annotation of the genes and other sequence elements that are encoded within the DNA. We remain largely ignorant of the detailed role of many genes in normal physiology, biochemistry and development and the genetic pathways involved. Moreover, there is a pressing need to elaborate the relationship between genes and disease susceptibility if the progress made in the human genome project is to be translated into a better understanding of pathophysiological mechanisms and a concomitant improvement in therapeutic approaches and health care. Deciphering the relationship between gene and phenotype in a mammalian organism represents one of the biggest challenges for genetics and biology in the twenty-first century. While some progress can be made through human genetic studies, studies of model organisms will be key to elaborating gene–phenotype space. In particular, the mouse will play a pivotal role as we embark upon a systematic and comprehensive functional annotation of the mammalian genome.

An extensive genetic toolbox has been developed for modifying the mouse genome, and we are now able to introduce mutations into coding and other sequences more or less at will. As a consequence, efforts are now underway to mutate every gene in the mouse genome (Austin *et al*., 2004; Auwerx *et al*., 2004), focusing mainly on a combination of two mutagenesis approaches – gene trapping (Stanford *et al*., 2001) and gene targeting (Glaser *et al*., 2005). The expectation is that over the next 5 years we will have access to comprehensive libraries of mouse mutants for every gene. Attention will then turn to mutating noncoding sequences, including transcribed noncoding sequences and putative regulatory elements. In order to interpret the relationship between gene (or DNA element) and phenotype, it is necessary, however, to determine the effects of each mutation on the various developmental and physiological pathways. It is also clear that any profound understanding of gene function will require that we undertake a comprehensive analysis of mouse phenotype that encompasses all adult body systems, as well as effects on developmental processes. Phenotyping even a minimal set of around

25 000 mutations, representing a single mutant allele at each gene in the mouse genome, will therefore be a phenomenal undertaking. While such a programme when complete would in itself represent a very significant milestone, it is only a useful beginning. It is also recognized that it will be important to generate and phenotype a number of mutant alleles at each gene locus with a range of potential effects if we are to develop a deep and systematic knowledge of gene function. Equally, the phenotypic effects of a mutant may vary according to genetic background, and there are persuasive arguments for determining the phenotype of each mutant on a variety of genetic backgrounds.

Given the enormous challenges involved in generating systematic datasets of phenotypes of mouse mutants, there has been much recent attention on the development of phenotyping approaches with a particular focus on the following:

- standardizing phenotyping approaches;
- developing high-throughput comprehensive phenotype screens;
- developing novel phenotyping platforms and new technological approaches to phenotyping;
- developing new standards for phenotype data representation.

Progress in each of these areas will bring us closer to our goal of providing a comprehensive phenotype database for gene function, which will be an intrinsic component of developing a systems biology of the mouse.

2. Standardization of phenotyping approaches

The phenotype assay is crucial to determining the measured output, and there is considerable evidence that the standard operating procedure (SOP) employed can have a marked impact upon the results of a particular test. The implication is that we need to standardize our approaches to phenotyping to ensure comparability of datasets across time and place. In addition, it is clear that environmental conditions, including cage environment (Tucci *et al*., 2006) and diet, may have a bearing upon the outcome of phenotype tests and need to be cataloged when acquiring phenotype data. Crabbe *et al*. (1999) found considerable variation between laboratories in behavioral test outcomes despite efforts to standardize procedures. Though the reasons remain unclear, it is possible that unrecognized factors in either test or environmental conditions contributed to the unwanted variation. Overall, it is clear that we need to study and document further the variables both in test and environment that contribute to variation in test outcome, and to further standardize the procedures for phenotyping platforms. Indeed, the Eumorphia project (European Union Mouse Research for Public Health and Industrial Applications, **http://www.eumorphia.org**, see below) has made a major effort to standardize and validate procedures for a variety of mouse phenotyping platforms both within and between laboratories (Brown, 2005). While many tests were validated, some SOPs demonstrated considerable variation in test output

between laboratories and thus require further examination and elimination of test variables.

3. Developing high-throughput comprehensive phenotype screens

One prevailing dogma in mouse phenotyping is to employ a hierarchical approach whereby initially rapid, comprehensive batteries of relatively unsophisticated tests are applied – the so-called primary screen. Subsequently, more sophisticated, but inevitably more time-consuming, secondary or tertiary screens may be carried out on specific animals depending upon the phenotypes revealed in the primary screen. The SHIRPA screen is an example of a test battery that employs this hierarchical approach (Rogers *et al*., 1997). However, there are no hard and fast boundaries between primary, secondary, and tertiary tests. Traditionally, there has been an inverse relationship between throughput and sophistication. However, one of the aims in mouse phenotyping is to encompass as many phenotype tests as possible within the envelope of the primary screen.

4. Developing novel phenotyping platforms and new technological approaches to phenotyping – the birth of the mouse clinic

There has been much progress in developing novel phenotyping platforms whereby we bring new technologies, along with advances in equipment and test design, to bear to enhance both the access and the throughput of even the most sophisticated tests. For example, even quite complex behavioral assays such as circadian rhythm screens have benefited enormously from automation and data capture and can be effectively utilized as primary screens. Microtechnologies and remote telemetric monitoring will aid a wide variety of phenotype procedures, while improvements in the application of a whole spectrum of imaging platforms (including MRI, SPECT, ultrasound, micro-CT) to the mouse are set to provide a new wealth of phenotype data (Brown *et al*., 2006). Individual systems have been the focus of innovative approaches, for example, the development of the optokinetic test in mice for the measurement of visual acuity (Thaung *et al*., 2002). New technologies such as Luminex will transform our ability to analyze a wide variety of blood proteins (de Jager *et al*., 2003). Moreover, the utilization of mice that carry reporter molecules will enhance cell lineage analysis and the monitoring of tissue structure.

The rapid expansion in the variety and complexity of phenotyping platforms poses a problem for the mouse genetics community. Even with the availability of well-documented and standardized procedures, it is unreasonable to expect every laboratory to have the expertise or the equipment to apply even a fraction of phenotyping platforms. The concept of the *mouse clinic* has emerged – institutions that possess a broad range of phenotyping expertise and offer these

as services to external users. Nevertheless, given the scale of the enterprise required to complete the functional annotation of the mouse genome, considerable investment in additional infrastructure will be required to meet future phenotyping demand.

5. New standards for phenotype data representation

Developing appropriate standards for representation of phenotype data is as critical as developing the standards in phenotype testing if we are to be able to apply the necessary computational tools to the datasets that will underpin and inform any systems analysis. However, the development of appropriate structures to represent phenotype data is only in the initial stage. One route that is being explored is to use ontological structures of the kind that have been employed for the Gene Ontology (Ashburner *et al*., 2000). Key to these developments in phenotype ontologies is the recognition that the phenotype assay is central to the description of phenotype – change the assay, even slightly, and the measured outcome may be different. For this reason, one approach that is being explored is to utilize a compound description of phenotype constructed from component ontologies that allows features such as the SOP, environmental conditions, genetic background, and so on, to be represented (Gkoutos *et al*., 2005).

Access to raw phenotype data is equally important and will allow us to mine important relationships in the context of genetic differences. To date, sizeable sets of raw phenotype data are available for the Mouse Phenome project ((Bogue and Grubb, 2004); **http://www.jax.org/phenome**) and at EuroPhenome (**http://www.europhenome.org**), where in both cases baseline data for a variety of inbred strains is available. Access to raw data coupled with standards on data representation and exchange will be critical if we are to harness the developments in phenotyping platforms and phenotype data acquisition to progress in dissecting gene–phenotype relationships and developing a systems biology of the mouse.

6. Conclusions

The challenges facing mouse genetics community as it embarks on the functional annotation of the mammalian genome are very considerable. First, there is the urgent need for further development of phenotyping platforms that will lead to improvements in the speed, cost, and sophistication of phenotyping tests. At the same time, it will be vital to ensure the standardization of phenotyping protocols, which will allow the generation of datasets from disparate research centers that can be shared and compared. Finally, we need to develop new informatics standards for data acquisition and representation that importantly include the phenotype test as a key variable. All of these challenges are being addressed as efforts get underway to undertake comprehensive phenotype analyses of mouse mutants from the worldwide mutagenesis programs.

Introductory Review

Bacterial pathogens of man

Julian Parkhill
The Wellcome Trust Sanger Institute, Cambridge, UK

Bacterial pathogens of man can be found in a number of different phylogenetic groups of bacteria, although their distribution amongst all the known genera of prokaryotes is somewhat patchy, and there is still a great deal of debate as to whether there are any pathogenic archaea. Genomic study of these pathogens has begun to identify some common themes amongst these organisms, but none that are truly universal, and has also served to underline the diversity of mechanisms utilized for virulence and host interaction. Comparative genomic analysis has also begun to indicate the different mechanisms by which these organisms may have evolved their specific interactions with the human host. Bacterial pathogenicity is not a discrete state, and these interactions can range from commensalism, where the disease outcome is accidental, through occasional, opportunistic pathogenicity in a generalist organism, to specialist pathogens that are dependent on the host. However, it is becoming increasingly clear that organisms can move between these categories over the course of evolution.

Some families of bacteria contain large numbers of human and animal pathogens, with the whole group seemingly specialized for interactions with eukaryotic hosts, and with many members capable of interaction with multiple hosts. One such family is the Enterobacteria (*see* Article 51, **Genomics of enterobacteriaceae**, Volume 4), which is named after its usual niche in the guts of mammals. Within this group are commensals, such as the nonpathogenic *Escherichia coli* K12 (Blattner *et al*., 1997), broad host-range pathogens, such as *Salmonella enterica* serovar Typhimurium (*S. typhimurium*) (McClelland *et al*., 2001), and symbionts, such as *Buchnera* and *Wigglesworthia* (Akman *et al*., 2002; Shigenobu *et al*., 2000). This group also includes arguably the most virulent human bacterial pathogen, that which causes plague, *Yersina pestis* (Parkhill *et al*., 2001a), and its less virulent relatives (*see* Article 58, ***Yersinia***, Volume 4). Within this group, genomic comparisons have been particularly fruitful, allowing comparison of pathogens and nonpathogens (e.g., *E. coli* O157:H7 (Perna *et al*., 2001) and *E. coli* K12 (*see* Article 51, **Genomics of enterobacteriaceae**, Volume 4)), broad host-range pathogens and host-restricted pathogens (e.g., *S. typhimurium* and *S. typhi* (Parkhill *et al*., 2001b)), and low-virulence organisms against highly virulent pathogens (e.g., *Yersinia pseudotuberculosis* (Chain *et al*., 2004) and *Y. pestis*). The genomic sampling of this family is already fairly broad, and is likely to get much deeper, with projects under way that are set to sample certain subgroups many times

over (see GOLD; **http://www.genomesonline.org**). Many useful and interesting insights have already been gained from the comparative genomic study of these organisms, not least the concepts of core gene sets and pathogenicity islands. Most of the organisms share a common set of core genes, often organized in the same order and orientation around the genome. These core genes are responsible for housekeeping functions, such as transcription, translation, central metabolism, and so on, as well as some functions that may be important for survival within the intestinal niche, such as motility and chemotaxis. Interspersed with these conserved regions are blocks of genes that confer specialist functions, such as interactions with a specific host, or particular virulence phenotypes. These accessory genes can be present in small groups of one, two, or more genes (sometimes called islets), or they can be clustered in larger islands containing tens of genes. These large islands (called pathogenicity or genomic islands) often carry specific mechanisms allowing insertion and excision from the chromosome, and sometimes transfer between bacterial cells, and are therefore self-mobile. In addition to these accessory genes on the chromosome, the enterics often carry plasmids encoding antibiotic resistance and virulence genes, and these can also be self-mobile. Comparative genomic analysis of enteric bacteria has also revealed that some host adaptations are relatively recent in evolutionary terms, and that despite the widespread acquisition of accessory genes, host restriction and adaptation can also be due to the loss of genes through mutation (Parkhill *et al*., 2001a), a process first described in *Rickettsia*.

Another group of organisms with a large range of different hosts and diseases and in which horizontal exchange of accessory DNA is widespread is the Streptococci (*see* Article 57, **Genome-wide analysis of group A *Streptococcus***, Volume 4). Amongst these organisms, the most deeply sampled species to date is *Streptococcus pyogenes* (Banks *et al*., 2004). *Streptococcus pyogenes* can cause a remarkable range of diseases, ranging from scarlet fever through toxic shock syndrome and impetigo to acute rheumatic fever. Many of the virulence factors of these organisms are carried on chromosomally integrated bacteriophage (prophage), which are clearly capable of horizontal spread, and indeed many of the significant differences between strains of the species are in the number and type of the prophage carried. A second medically important Streptococcal species is *S. pneumoniae*, which is one of the causative agents of bacterial meningitis, but usually lives as a commensal in the throat. Several *S. pneumoniae* genomes have been, or are being, sequenced (Tettelin *et al*., 2001), including that of the strain in which DNA was first demonstrated to be the genetic material (Avery *et al*., 1944; Hoskins *et al*., 2001), and they indicate a far greater role for exchange of, and variability in, chromosomal genes in driving diversity in this species. Much of this is likely to be due to the fact that *S. pneumoniae* is a naturally competent organism, and is capable of taking up DNA from the environment and integrating it into its chromosome directly. Despite these, and other, studies, the link between genome content, virulence, and carriage in this species is far from clear, and several more genomic sequences are planned in order to attempt to shed more light on this. The genus *Streptococcus* also includes several important animal pathogens, and genomic projects for many of these are ongoing.

Like *S. pneumoniae*, several organisms often considered to be out-and-out pathogens are really commensals, and only cause disease accidentally, or when in a nonnatural host. A good example of this type of organism is *Neisseria meningitidis* (*see* Article 62, **The neisserial genomes: what they reveal about the diversity and behavior of these species**, Volume 4). While it is capable of causing two of the most fulminant and feared diseases, meningitis and septicaemia, its real niche is as a commensal of the human throat, a site to which it is extremely well adapted. Surprisingly, causing invasive disease is an evolutionary dead end for the specific organisms that escape into the blood stream – they cannot subsequently transmit to another host. For this reason, genomic investigation is aimed at those strains that are more likely to cause invasive disease, but the analysis must take into account the fact that adaptations identified in the genome are selected for commensal growth and transmission, not virulence.

A second type of accidental pathogen is that which is adapted to commensal existence in one host, but causes disease in another. A specific example of this is *Campylobacter jejuni*, which is a commensal of birds (its growth optimum is 42°C, the internal temperature of the chicken gut). When ingested by humans (in undercooked food), it causes gastroenteritis. *Campylobacter jejuni* is from the epsilon group of the proteobacteria, and its genome (Parkhill *et al*., 2000) revealed few of the well understood pathogenicity determinants that had mainly been discovered in the gamma proteobacteria (which includes the well-studied enterics), such as type-III and IV secretion systems, pili, and so on, and there was no evidence for classical pathogenicity islands (*see* Article 61, **Comparative genomics of the ε-proteobacterial human pathogens *Helicobacter pylori* and *Campylobacter jejuni***, Volume 4). Much of the basis of *Campylobacter* virulence is still unknown, although it is known that the flagellar system (which has been shown to secrete proteins in lieu on a type-III system (Konkel *et al*., 2004)) and surface polysaccharides are important. Perhaps surprisingly, one of *Campylobacter*'s closest sequenced relatives, *Helicobacter*, is an obligate resident of human beings (*see* Article 61, **Comparative genomics of the ε-proteobacterial human pathogens *Helicobacter pylori* and *Campylobacter jejuni***, Volume 4). *Helicobacter pylori* colonizes the stomach, and can cause ulcers and gastric cancer. The *H. pylori* genome is highly recombinogenic (Suerbaum *et al*., 1998), and encodes a well-defined toxin-encoding pathogenicity island. Curiously, *H. pylori* transmission seems to be primarily vertical, to the extent that population analysis of *H. pylori* can be used to define the structure and movements of human populations over millennia (Falush *et al*., 2003).

Another group of pathogens is the generalists, which are capable of survival and growth in many different environmental niches, including humans, other animals, and plants. These bacteria tend to have large and often complex genomes, and include species from the Burkholderiaceae and Pseudomonads. *Burkholderia pseudomallei*, for example, is generally a soil-dwelling saprophyte, but can infect humans (causing the disease meliodosis). The genome of *B. pseudomallei* is large (>7.2 Mb in two chromosomes), and contains evidence for large numbers of mobile islands, as seen in the Enterobacteriaceae, many of which are involved in metabolic diversity and environmental survival rather than simply pathogenicity (Holden *et al*., 2004). In this sense, *B. pseudomallei* may view the eukaryotic cell as

just another environment that can be exploited. Another opportunistic pathogen with similar abilities to survive in a wider environment and infect humans is *Pseudomonas aeruginosa* (Stover *et al*., 2000), which can cause lung infections in Cystic Fibrosis patients, and can also infect serious skin burns.

At the other end of the scale are pathogens that have specialized to the extent that they can no longer survive outside their chosen host. Classical examples of these are the Spirochetes (*see* Article 60, **Spirochete genomes**, Volume 4), which include the agents of syphilis (*Treponema pallidum*) and Lyme disease (*Borrelia burgdorferi*), and the Chlamydiales (*see* Article 59, **Chlamydiae**, Volume 4), which are obligate intracellular pathogens, and include the cause of trachoma (*Chlamydia trachomatis*). These organisms are so specialized that they are often very difficult to grow in the laboratory, and genomics is usually the most effective, and sometimes the only, way of getting genetic information about these organisms. These host-obligate organisms tend to have compact genomes, with a large degree of gene loss and evidence of metabolic streamlining. This process has been taken almost to completion in the Mycoplasmas (*see* Article 53, **The Mycoplasmas – a congruent path toward minimal life functions**, Volume 4). These organisms rely on their host for many nutrients and metabolites, and have reduced their metabolism to the extent that they can no longer make a cell wall. This is evident in their extremely small genomes (<600 kb in some cases), and it is this that has made them attractive tools for attempts to identify the smallest genome capable of supporting life (Hutchison *et al*., 1999).

Some bacterial genera contain organisms exhibiting many of these different characteristics, indicating the relative ease with which bacteria can move between categories during evolution. A good example of this is the Mycobacteria (*see* Article 52, **Genomics of the *Mycobacterium tuberculosis* complex and *Mycobacterium leprae***, Volume 4), which contains generalists with large genomes (e.g., *M. smegmatis*), specialist pathogens with smaller genomes and evidence for host-specialization with small genetic changes (e.g., *M. tuberculosis* and *M. bovis* (Cole *et al*., 1998; Garnier *et al*., 2003)), and host-obligate pathogens with highly reduced genomes (e.g., *M. leprae* (Cole *et al*., 2001)). These organisms are also extremely successful, causing some of the most common and feared infections in human history, including tuberculosis and leprosy.

In summary, it can be seen that bacterial pathogens are not a coherent group of organisms; they come from a wide variety of backgrounds and use a large diversity of strategies for host interaction. All of this makes the study of bacterial pathogen genomes an exciting and interesting pursuit, with the real potential for contributing to the control and elimination of human diseases (*see* Article 55, **Reverse vaccinology: a critical analysis**, Volume 4).

Introductory Review

Eukaryotic parasite genome projects

Neil Hall

The Institute for Genomic Research, Rockville, MD, USA

1. Introduction

Parasites cover a diverse range of organisms from bacteria such as *Mycobacterium leparae* (*see* Article 52, **Genomics of the *Mycobacterium tuberculosis* complex and *Mycobacterium leprae***, Volume 4) to unicellular protists such as the malaria parasite *Plasmodium falciparum* and multicellular eukaryotes such as nematode worms or arthropods; in this chapter, I will be concentrating primarily on work carried out on protist and nematode genomes. At the time of writing, there have been only two complete eukaryotic parasite genomes published (Gardner *et al*., 2002; Katinka *et al*., 2001). However, there are over 30 ongoing genome projects that are releasing data freely onto the Internet, and are already influencing how researchers are designing experiments and are contributing to the development of new treatments, diagnostic tests, and surveillance mechanisms. Parasite genomes can be large and complex and, unlike in the case of bacteria, few parasite genomes have yet been sequenced to completion, and researchers are often reliant on using partial genome data or Expressed Sequence Tag (EST) data (*see* Article 78, **What is an EST?**, Volume 4). In this chapter, I will attempt to describe how genome data has provided useful insights into parasite biology, evolution, and treatment, in each case highlighting specific examples.

2. Biological insights

In most eukaryotic organisms, each gene is associated with its own promoter region, which regulates the transcript level of the gene so that the protein encoded by it is only produced when required. When chromosome I of the *Leishmania major* genome was sequenced, it revealed one of the most unusual aspects of kinetoplastid biology; all of the genes are arranged in linear blocks, which are now believed to be transcribed as single polycictronic transcription units radiating from a single "strand switch region" (Myler *et al*., 1999). Hence, many genes appeared to share a single promoter. This model has many similarities to bacterial transcription in which genes are organized into functional operons that form a single transcript, although in *L.*

major the genes within the transcription units are not functionally clustered, so need not necessarily be coregulated. Now that the full genome of *L. major* has been sequenced, along with the genomes of the related parasites of *Trypanosome brucei* and *Trypanosome cruzi*, the causative agents of African sleeping sickness and Chagas' disease respectively (Degrave *et al*., 2001), researchers have observed that the same mechanism of transcription is present in all of these species and they are turning their attention to how the genes are regulated in systems that appear to lack conventional promoters. Because the genome data has been made freely available, scientists are able to use techniques that would otherwise be impossible, such as microarrays that allow them to measure expression levels of all of the genes in a genome (*see* Article 90, **Microarrays: an overview**, Volume 4 Section 8), and proteomics (see Volume 3) which measures the expression of all the proteins encoded by the genome. It now appears that the genes are regulated by post transcriptional mechanisms, whereby RNA transcript processing controls how much messenger RNA is translated into protein (reviewed in Horn, 2001).

3. Evolution

Many parasites occupy interesting positions in the phylogentic tree of life. Some protist parasites are believed by some to be examples of early branching eukaryotes, such as the kinetoplastids and the amitochondriates (*Entamoeba*, *Giardia*, *and Trichomonas*), whereas the nematodes are a highly diverse group of organisms that provide useful comparisons to the model free-living nematode *C. elegans* (*see* Article 44, **The *C. elegans* genome**, Volume 3). The intracellular parasite *Encephalitozoon cuniculii* is a microsporidial fungus, which has reduced its genome size as it has evolved as an obligate parasite, and numerous cellular functions have been taken on by the host. The genome is tiny for an eukaryote (2.9 Mb) encoding only 2000 genes (Katinka *et al*., 2001). It was believed that microsporidia did not have mitochondria and that they could represent a lineage of eukaryotes that branched before the acquisition of mitochondria. However, the genome project found many genes that appeared to have mitochondrial functions, and it is now thought that a cryptic mitochondrion, that has lost its genome and many of its functions, is present.

Plasmodium falciparum contains an organelle (intracellular structure) called the apicoplast that is found in almost all apicomplexan parasites. Sequencing of the apicoplast genome revealed that it is orthologous to the plant chloroplast (although clearly no longer photosynthetic), and it is believed to have evolved via a process of secondary endocytosis, whereby an algal cell became enslaved by another eukaryotic cell (McFadden, 2000). When the first data became available from the *P. falciparum* nuclear genome project, it was noticed that *Plasmodium* was littered with genes that appeared to be plant-like in origin. These genes were most likely transferred to the nuclear genome from the ancient algal cell. Many of these genes produce protein products that are directed back to the apicoplast. It is now estimated that nearly 10% of the genes in the *Plasmodium* genome encode products that end up in the apicoplast, demonstrating how important the organelle is for the parasite (Foth *et al*., 2003; Gardner *et al*., 2002). This finding has made the apicoplast an

attractive drug target as it carries out many metabolic functions that are not found in the vertebrate host.

4. Drug targets

A major objective of scientific research into parasitic diseases is to identify new drug targets or to understand better the mode of action of existing drugs. Up until recently, much of this study has relied on traditional biochemical methodology; however, since the advent of genomics, biochemists have been able to direct research based on a better understanding of the organism's metabolic potential.

Once a genome has been sequenced and annotated, all of the metabolic enzymes encoded within it can be identified. These genes are often well conserved and therefore simple to find and can be pieced together into complete metabolic pathways. After all of the pathways have been identified, one can focus on research of those enzymes that are potentially good targets for inhibition either because there are existing drugs that act on them or because they are absent from the host organism and hence drugs could better target the parasite. When the genome of the malaria parasite *P. falciparum* was sequenced, researchers identified genes encoding enzymes for the type II fatty acid biosynthesis pathway. This pathway in bacteria was the target for a drug called Triclosan, which has since been tested against *Plasmodium* and proven to be effective (Surolia and Surolia, 2001). Since then, whole genome analysis has highlighted seven new pathways that were, in some way, unique to the parasite compared to the human host, and hence may be good drug targets (Gardner *et al*., 2002).

5. Forward genetics

For parasites that go though a sexual cycle such as *T. brucei* and *P. falciparum*, genetic mapping can be used to pinpoint DNA sequences that contribute to heritable phenotypes: This is known as *positional cloning* or *forward genetics*. This technique becomes a powerful research tool once a genome sequence can be overlaid onto a genetic map as this positions genes relative to the map. In the case of *T. brucei*, a genetic map of the entire genome has been generated and is being used to map drug resistance and virulence traits (Tait *et al*., 2002). The genetic map of *P. falciparum* has been successfully employed to localize the gene conferring resistance to chloroquine (*see* Article 9, **Genome mapping overview**, Volume 3) (Su *et al*., 1999; Su and Wellems, 1996).

6. Antigen discovery

Early data from the *P. falciparum* genome project revealed that many of the major antigens were located at the telomeres of the chromosomes, most notably, the *VAR* genes that encode Pfemp1 proteins that are expressed on the surface of infected

red blood cells (Bowman *et al*., 1999; Gardner *et al*., 1998). Because of this, researchers concentrated efforts on studying the other telomeric genes, some of which have since been identified as being involved in an antigenic variation or host interaction such as the *RIFIN* and *STEVOR* genes. The complete genome sequence has allowed us to identify all of the genes in these families, which is an important step in identifying useful domains for vaccine design and understanding the complex processes involved in the host parasite interaction. Other *Plasmodium* species have been partially sequenced (*Plasmodium vivax*, *Plasmodium berghei*, *Plasmodium chabaudi*, and *Plasmodium yoelii*), and this has shown that these parasites have different telomere structures and different antigens encoded in them, known as *VIR* genes (del Portillo *et al*., 2001; Fischer *et al*., 2003; Janssen *et al*., 2001; Janssen *et al*., 2002) (also known as *BIR*, *CIR*, or *YIR* genes, depending on which species they are found in). These *VIR* genes are also thought to be involved in antigenic variation and expressed on the red blood cell surface (del Portillo *et al*., 2001).

It may be some time before genome data will be converted into marketable treatments, but sequencing projects have clearly heralded a new era in parasite research and are driving development into new drugs and vaccines, as well as contributing massively to our understanding of parasite molecular biology. In the next few years, it is likely that more than 30 parasite genomes will be sequenced so the full impact of this tidal wave of data is yet to be felt.

Specialist Review

Genomics of enterobacteriaceae

Jeremy D. Glasner and Nicole T. Perna
University of Wisconsin, Madison, WI, USA

1. Introduction

Enterobacteria were among the earliest targets for genome sequencing and are still the most densely sampled clade of bacteria in the genomics arena. Twenty complete genome sequences are available for members of the family as of September 2004, and the NCBI list of genomes in progress includes another 20 enterobacteria. This is undoubtedly an underestimate of the sequences that will be available for enterobacteria in the coming two years. Among the complete genomes are representatives of nine genera, including *Escherichia*, *Shigella*, *Salmonella*, *Yersinia*, *Erwinia*, *Buchnera*, *Photorhabdus*, *Wigglesworthia,* and *Candidatus Blochmannia*. Genomes in progress will add additional strains and species of these, as well as additional genera such as *Klebsiella*, *Proteus*, *Citrobacter*, *Enterobacter*, *Dickeya*, and *Pantoea*. Among these are standard laboratory research strains, human pathogens, livestock pathogens, plant pathogens, and insect endosymbionts. Each genome sequence aids in understanding the biology of the individual organism, but some of the greatest insights come from comparisons between the genomes. For many of these genera, sequences are available for multiple species or strains, providing unique perspectives on genome-wide polymorphism. Enterobacteria are also very experimentally tractable, and we are beginning to see a boom in downstream research making use of the sequences.

2. A brief history

The first enterobacterium chosen for complete genome sequencing was *Escherichia coli* K-12 strain MG1655 (Blattner *et al*., 1997; Perna *et al*., 2002), motivated by the widespread use of this model prokaryote for molecular biological research and industrial applications. To this day, *E. coli* K-12 remains one of the best-studied organisms on earth, with direct experimental evidence for the functions of a large number of genes. Data from high-throughput postgenomic experimentation with other strains or species may quickly eclipse the volume of data currently available for *E. coli* K-12. However, data from proteomic and functional genomic techniques tend to generate hypotheses that must be tested by more detailed experimental characterization. For this reason, *E. coli* K-12 with its long history of experimental

investigation continues to play a special role in genomics of all enterobacteria, and perhaps all prokaryotes, as the ultimate source of most experimental evidence used to attribute gene functions in genome annotation.

Following *E. coli* K-12, two groups of organisms were next in line for genome sequencing and remain active areas of inquiry. These are pathogens of humans and other animals (reviewed in Whittam and Bumbaugh, 2002), which were chosen for their biomedical relevance and distinctive disease potentials. Continued sequencing efforts in this area are justified by the astounding diversity seen in initial comparisons of these genomes and the number of different species that colonize the guts and are often associated with disease of humans and livestock. The other group is insect symbionts that were chosen as a model for studying microbe–insect interactions and evolution by genome reduction (Tamas *et al*., 2002; Shigenobu *et al*., 2000; Moran, 2003). Genome-sequencing efforts for plant-pathogenic enterobacteria lagged behind, but this deficit is being addressed with one recently published (Bell *et al*., 2004) and at least three ongoing projects.

3. Evolution of genome content and size in enterobacteria

Sequenced genomes of enterobacteria vary over an order of magnitude in length (0.62–5.59 million base pairs (Mbp)) and correspondingly, in number of predicted genes (504–5476), as shown in Table 1. Typical genome architecture is a single bidirectionally replicating circular chromosome and one or more circular plasmids. One striking observation is the extreme difference in genome sizes observed between free-living organisms and the insect endosymbionts, *Buchnera*, *Wigglesworthia*, and *Blochmannia*. The apparent simplicity of the idea of genome reduction as a consequence of an obligate relationship with a host belies the complexity of the evolutionary dynamics behind even these streamlined genomes. There are several insightful reviews on the subject (Moran, 2003; Klasson and Andersson, 2004; Wernegreen, 2002). Comparative analysis of the five complete genomes from insect endosymbiotic bacteria revealed only 277 protein-coding genes in common (Gil *et al*., 2003).

All genes in the symbionts are also found in the free-living enterobacteria. These clearly represent a subset of the genes present in the most recent common ancestor (MRCA) of all enterobacteria since many genes not found in the symbionts have orthologs in more distantly related bacteria. Moran *et al*. estimate that there were 2425 genes in the MRCA genome (Moran and Mira, 2001). Robust phylogenetic evidence supports the idea of a common lineage leading to all the sequenced insect endosymbiotic enterobacteria (Lerat *et al*., 2003). While deletions of the ancestral chromosome clearly shaped this lineage, other enterobacteria show extensive evidence of both loss and gain of genes. Acquisition of clusters of genes from other strains and species by horizontal transfer appears to be relatively common in free-living enterobacteria. Not so long ago, this observation disrupted a paradigm of clonal evolution for bacteria in general, based on considerable work with enterobacteria in particular (Smith *et al*., 1993). The significant role recombination plays in enterobacterial genome evolution is now quite clear.

Table 1 Published complete genome sequences from enterobacteria

General information	Species and strain	Genome length (bp)	Number of plasmids	Number of genes[a]	References
Common K-12 laboratory strain	*Escherichia coli* strain MG1655	4 639 675	0	4269	Blattner *et al*. (1997)
Enterohemorrhagic pathogen associated with outbreak in Japan	*Escherichia coli* serotype O157:H7 strain Sakai	5 498 450	2	5470	Hayashi *et al*. (2001)
Example of virulent serogroup 2a associated with dysentery	*Shigella flexneri* serotype 2a strain 301	4 607 203	1	4186	Jin *et al*. (2002)
Example of virulent serogroup 2a associated with dysentery	*Shigella flexneri* serotype 2a strain 2457 T	4 599 354	0	4073	Wei *et al*. (2003)
Enterohemorrhagic pathogen from meat linked with outbreak	*Escherichia coli* serotype O157:H7 strain EDL933	5 528 445	2	5346	Perna *et al*. (2001)
Urinary tract pathogen associated with pyelonephritis	*Escherichia coli* strain CFT073	5 231 428	0	5379	Welch *et al*. (2002)
Standard laboratory model system for Salmonella research	*Salmonella enterica* serovar Typhimurium strain LT2	4 857 432	1	4451	McClelland *et al*. (2001)
Multiple drug resistant pathogen associated with typhoid fever	*Salmonella enterica* serovar Typhi strain CT18	4 809 037	2	4600	Parkhill *et al*. (2001a)
Model strain for work with typhoid fever associated Salmonellae	*Salmonella enterica* Serovar Typhi strain Ty2	4 791 961	0	4323	Deng *et al*. (2003)
Human pathogen associated with bubonic and pneumonic plague	*Yersinia pestis* strain KIM	4 600 755	2	4280	Deng *et al*. (2002)
Recently isolated human pathogen associated with plague	*Yersinia pestis* strain CO92	4 653 728	3	4008	Parkhill *et al*. (2001b)
Human avirulent strain isolated from a rodent	*Yersinia pestis* strain 91001	4 595 065	4	3895	Song *et al*. (2004)
Pathogen associated with chronic but mild intestinal disease	*Yersinia pseudotuberculosis* strain IP32953	4 744 671	2	3974	Chain *et al*. (2004)

(*continued overleaf*)

Table 1 (*continued*)

General information	Species and strain	Genome length (bp)	Number of plasmids	Number of genes[a]	References
Plant pathogen associated with soft-rot and blackleg of potatoes	*Erwinia carotovora atroseptica* strain SCRI1043	5 064 019	0	4491	Bell *et al*. (2004)
Symbiont of nematodes and insect pathogen	*Photorhabdus luminescens* strain TT01	5 688 987	0	4905	Duchaud *et al*. (2003)
Endocellular symbiont of the aphid species *Baizongia pistacea*	*Buchnera aphidicola* (*Baizongia pistacea*)	615 980	1	504	Tamas *et al*. (2002)
Endocellular symbiont of the pea aphid species *Acyrthosiphon pisum*	*Buchnera* sp. APS	640 681	1	564	Shigenobu *et al*. (2000)
Endocellular symbiont of the aphid species *Schizaphis graminum*	*Buchnera aphidicola* (*Schizaphis graminum*)	641 454	1	545	Tamas *et al*. (2002)
Endocellular symbiont of carpenter ants	*Blochmannia floridanus*	705 557	0	589	Gil *et al*. (2003)
Endocellular symbiont of tsetse flies	*Wigglesworthia brevipalpis*	697 724	0	611	Akman *et al*. (2002)

[a]Number of protein-coding genes on the main chromosome reported in the ASAP database as of September 15, 2004 (Glasner *et al*., 2003).

Multilocus enzyme electrophoresis profiles from numerous comparisons of enterobacterial strains and species showed strong linkage disequilibrium, supporting a common evolutionary history for genes distributed throughout the chromosome, hence, clonal evolution. At odds with this model were analyses of early segments of the *E. coli* K-12 genome sequence, which revealed a significant number of genes with atypical codon usage and other nucleotide biases suggesting origins from other bacteria with fundamentally distinct compositional signatures (Medigue *et al*., 1991). Also, before completion of the first genome, researchers coined the term "pathogenicity island" to describe clusters of genes associated with virulence found specifically in pathogenic strains (Morschhauser *et al*., 1994). These islands also showed unusual nucleotide composition, and some could be mobilized and transferred among strains or species. Comparisons of complete genome sequences provided a unified framework for all these observations and expanded the concept of islands.

Alignment of even relatively closely related pairs of genomes, like two strains of *E. coli,* reveals hundreds of lineage-specific islands interspersed among conserved segments of the chromosome. More than a quarter of an *E. coli* genome can lie within these islands (Perna *et al*., 2001; Hayashi *et al*., 2001; Welch *et al*., 2002). They encode a wide variety of activities associated with diverse processes including but not limited to pathogenesis, and some interesting examples of islands in particular genomes are highlighted below.

Despite the apparently high levels of horizontal transfer introducing new DNA into the chromosomes of enterobacteria, replacement of existing alleles with divergent copies from other lineages is uncommon. Genome-scale phylogenetic analyses of the genes from the core chromosome repeatedly support the same branching order, or topology, for subsets of enterobacteria, consistent with the multienzyme electrophoresis data (Daubin *et al*., 2003; Lerat *et al*., 2003). The "Core Genome Hypothesis" has been described as an application of the biological species concept to bacteria (Wertz *et al*., 2003).

4. *E. coli* and *Shigella*

E. coli and *Shigella* will be treated as a group in light of overwhelming phylogenetic and genomic support for the idea that they are the same species (reviewed in Lan and Reeves, 2002). Sequences are complete and published for laboratory *E. coli* K-12 strain MG1655, two enterohemorrhagic *E. coli* O157:H7 strains (EDL933 and O157 Sakai), a urinary tract-associated *E. coli* strain (CFT073), and two *S. flexneri* strains (301 and 2457 T).

O157:H7 genome sequencing and comparison to K-12 was instrumental in revealing the extent of horizontal gene transfer in this species. Genomes of O157:H7 are also of considerable interest as important human pathogens, and many genes potentially relevant to disease were discovered or better characterized by genome sequencing. O157:H7 strains cause a bloody-diarrhea (hemorrhagic colitis), and occasionally infections lead to fatal hemolytic uremic syndrome (HUS). Two independent O157:H7 genomes have been sequenced and show very few differences in gene content and chromosome organization. Examination of the O157:H7 genomes revealed about 1.5 Mb of sequences that are not conserved with *E. coli* K-12 clustered into over 150 islands. Genes encoded within these islands include a well-known type III secretion system (LEE), as well as a second, previously uncharacterized cryptic type III secretion system now known to be widely distributed, albeit with substantial divergence, among *E. coli* strains (Ren *et al*., 2004). The islands also included a collection of fimbrial and nonfimbrial adherence factors, putative toxins, and iron utilization systems, many of which have subsequently been characterized with clear roles in pathogenesis. The sequence of the 92-Kb virulence plasmid revealed a large putative toxin, with a newly demonstrated role in adherence to epithelial cells and type III secretion (Stevens *et al*., 2004). The O157:H7 genomes are also rich in prophages, with at least 18 regions from each genome showing similarity to known phages. These include the functional prophages (933 W in EDL933 and VT2-Sakai from O157Sakai) that encode the characteristic shiga-like toxins. Interestingly, many strains, including the

two genomes sequenced, include a second set of shiga-like toxin genes encoded in the analogous position of a cryptic prophage, and the phage regions flanking the toxins are conserved with many other lambda-family phages in these and other genomes (Ohnishi *et al*., 2001). The position of these genes, in a late-phage transcript, provides insight into the regulation and dissemination of the toxin genes in the *E. coli* population. This may prove important in understanding the emergence of other distinct lineages of shiga-like toxin producing *E. coli* (STEC). Genome sequences for other STEC strains could reveal other genes associated with convergent evolution of hemorrhagic phenotypes emerging from distinct lineages of *E. coli* that arose by independent horizontal transfers of similar islands. No sequencing projects for other STEC are currently underway, although at least one representative STEC genome may be included in a newly funded effort.

Shigella are also important human pathogens associated with dysentery, particularly in developing countries. The two sequenced *S. flexneri* genomes are relatively small (4.59 and 4.60 Mb) and show more examples of chromosome rearrangement than other sequenced *E. coli* genomes (Jin *et al*., 2002; Wei *et al*., 2003). The gene content of strains 301 and 2457 T are very similar, but several major rearrangements are detectable (Wei *et al*., 2003; Darling *et al*., 2004). At least 15 genome rearrangements differentiate strain 2457 T from *E. coli* K-12, compared to the single inversion seen between O157:H7 EDL933 and K-12. Alignment of *Shigella* and K-12 genomes delineates 37 islands larger than 1 kb in length. These islands along with the *Shigella*-associated plasmids encode many of the known and putative virulence factors. These include a type III secretion system associated with invasion, iron uptake systems, and adherence factors. This list sounds qualitatively similar to the genes that distinguished O157:H7 strains from K-12. However, comparisons of genes from the *Shigella* islands with homologs in O157:H7 reveal differences in chromosomal locations of the genes and high levels of sequence divergence. This suggests that these islands likely arose as independent horizontal transfer events.

The *S. flexneri* genomes have a large number of IS elements relative to other *E. coli* strains, and many of the genome rearrangements are bounded by copies of the same element. The IS abundance is also obvious on the virulence plasmids. The plasticity observed in *Shigella* genome sequence comparisons illuminates a possible underlying basis for high levels of PFGE polymorphism among epidemiologically relevant *Shigella* isolates. A large number of pseudogenes (372) relative to other *E. coli* are also related to IS activity and, interestingly, account for many of phenotypic characters used as *Shigella* diagnostics (Wei *et al*., 2003). Although serotype 2a is particularly virulent, these two genomes barely begin to represent the diverse *Shigella* relevant to human health. Sequencing of genomes from additional *Shigella* species (*S. dysenteriae* and *S. boydii*) is underway.

Extraintestinal *E. coli*, like pyelonephritis-associated strain CFT073, are also of interest. *E. coli* are responsible for 70–90% of urinary tract infections. Strain CFT073 is also a member of one of the earliest diverging branches of *E. coli,* and this phylogenetic position makes it particularly useful for interpreting the evolutionary history of the species. Co-occurrence of islands in the CFT073 genome at the same location as distinct islands in O157:H7 and/or K-12 suggests reuse of chromosomal sites for successive horizontal transfers. This could be due to
